PRIVATE LIBRARY

— OF —

JAMES E. TALMAGE,

SALT LAKE CITY, UTAH.

CLASS. B

NO. 3461

J. Woolfe, Pinx.

G. Cook, Sculp.

PROFESSOR LEOPOLD GMELIN, M.D., F.R.S.

LATE OF THE UNIVERSITY OF HEIDELBERG.

Leopold Gmelin

WILLIAM MACKENZIE, GLASGOW, EDINBURGH, LONDON & NEW YORK.

Chemistry

THEORETICAL, PRACTICAL & ANALYTICAL.

AS APPLIED AND RELATING TO

The Arts and Manufactures.

BY

DR SHERIDAN MUSPRATT F.R.S.E. M.R.I.A. F.G.S.

VOL. II.

UNIVERSITY OF CALIFORNIA

U.V. 8
V. 12
HATU. 00000

DR BLACK.

PROFESSOR OF CHEMISTRY, GLASGOW & EDINBURGH.

Joseph Black

Engraved by W. Cook from a Photograph.

PROFESSOR BUNSEN.

OF THE UNIVERSITY OF HEIDELBERG.

W. Bunsen.

PROFESSOR CHEVREUL.

PROFESSOR OF APPLIED CHEMISTRY AT THE GOBELIN MANUFACTORIES: AND EXAMINER IN THE ARTS OF THE MANUFACTURES.

E. Chevreul

CHAPTAL.

LATE PROFESSOR OF CHEMISTRY AT MONTPELLIER.

Le. It. of

Engraved from a photograph by Muller.

A. Christie

From a Photograph by Beard

PROFESSOR FARADAY, D.C.L., F.R.S., &c.

PROFESSOR IN THE ROYAL INSTITUTION OF GREAT BRITAIN

Michael Faraday

From a lithograph by G. Jones.

C. G. Smith.

GEORGE FOWNES F.R.S.

LATE PROFESSOR OF PRACTICAL CHEMISTRY IN UNIVERSITY COLLEGE, LONDON.

Geo. Fownes

William Gregory

Engraved by Cook from an original portrait

PROFESSOR A.W. HOFMANN L.D.

OF THE GOVERNMENT SCHOOL OF MINES

A.W. Hofmann

Engraved by C. Davis from an original photograph

BARON JUSTUS LIEBIG M.D. F.R.S. &c.

PROFESSOR IN THE UNIVERSITY OF MUNICH

Justus von Liebig

PROFESSOR MITSCHERLICH F.R.S.E.

ROYAL UNIVERSITY OF BERLIN

E. Mitscherlich.

PROFESSOR OF CIVIL MILITARY, NEW YORK.

Campbell Morfit.

A Claudet.

G Cook.

DR LYON PLAYFAIR, C.B. F.R.S.

PRESIDENT OF THE CHEMICAL SOCIETY

Lyon Playfair.

JOHN PRINGLE, Esq. F.R.S.

J.G. Gilbert.

C. Cook.

THOMAS THOMSON, M.D., F.R.S.

LATE PROFESSOR OF CHEMISTRY AT THE UNIVERSITY OF GLASGOW.

Thomas Thomson

Altemend

1840

PROFESSOR WÖLLER

OF THE UNIVERSITY OF GÖTTINGEN

Wöller.

WILLIAM HYDE WOLLASTON, M.P.

Wm H Wollaston

STEREOTYPED AND PRINTED BY WILLIAM MACKENZIE, GLASGOW.

INDEX TO ARTICLES.

VOL. II.

FUEL—1-118.

absorbent power of different bodies for caloric, 13.
analyses of, 103-106.
" of different coals, 76-85.
American coals, composition of, 79.
anthracite, 75.
" heating effect of, 113.
artificial fuel, 97.
ash, amount of, in charcoals, 43.
" " in different woods, 32.
" from bituminous coals, 77, 78.
" from lignites, 76.
BAILLET's carbonizer, 41-43.
BARLOW's estimate of expansive force, 4.
BERARD's coal-washing machine, 95.
BERTHIER's analyses of fuels, 106.
BESSEMER's patent fuel, 100-103.
bituminous coals, analyses of, 77, 78.
Boghead coal, 83-85.
BRUNE's meller process, 40.
BUFFON's experiment with reflectors, 2.
caking coal, 74.
caloric, 1, 2.
" latent, 18-20.
CALVERT's patent for desulphurizing coke, 96.
cannel coal, 75, 85.
" coalfields, section of, 84.
carbon, 33.
" and hydrogen, as combustibles, 25.
carbonization, 33-46.
" of peat, 63-68.
" of coal, 85-103.
centigrade thermometer, 3.
charcoal, absorbent power of, 48.
" amount produced at different temperatures, 35.
" analyses of, 47.
" ash in, 48.
" combustion of, 49, 50.
" densities of, 48, 49.
" heat-conducting power, 49.
" from peat, 111, 112.
" from wood, 33-50, 111, 112.
" quality of, 47.
chemical action, a source of heat, 2.
cherry, or soft coal, 75.
coal, 68-85.
" American, composition of, 79.
" analyses of, 97.
" bituminous, 77, 78.
" carbonization of, 85-103.
" chemical characteristics, 69.
" composition of, 70, 75-85.
" Derbyshire, 81.
" distribution of, 70-73.
" heating effect, 111, 112.
" Lancashire, 81.
" microscopic characters, 69.
" mineralogical characters, 68.
" Newcastle, 80.
" origin of, 68.
" products of distillation, 86.
" Scotch, 81, 85.
" soft, 75.
" Torbanehill, 83-85.
" varieties of, 74, 75.
" washing, 94-96.
" Welsh, 80.
coalfields in British isles, 72.
" in United States, 71.
COBBOLD's method of preparing peat, 56.
coke, 33, 85-103.
" heating effect of, 111, 112.
cold, produced artificially, 19.
combustibles, heating power of, 107.
" relative value of, 24.
combustion, 2, 23.
" products of, 33.

FUEL, continued.

conduction of heat, 7-10.
convection of heat, 10, 11.
CRANE's carbonizing furnace, 67.
crystalline bodies, conducting power of, 9.
DANIELL's pyrometer, 5.
density of different woods, 27, 28.
DESPRETZ on conductivity of metals, 8.
diathermous bodies, 14-16.
differential thermometer, 13.
distillation of wood, 45.
DULONG and ARAGO's experiments on elasticity of high-pressure steam, 23.
ebullition and evaporation, 20-22.
electricity, heat produced by, 2.
estimation of heating power of different kinds of fuel, 106-118.
expansion of solids, 4-6.
" liquids, 6, 7.
" gases, 7.
expansive action of caloric, 2.
FAHRENHEIT's thermometer, 3.
fluidity, heat of, 18.
FOUCAND's carbonizer, 41.
fracture by sudden heating, 5.
French patent fuel, 97.
friction, a source of caloric, 2.
frigorific mixtures, 19.
furnace, coking, 90-94.
furnace, precautions in constructing, 9.
gases, convection of heat by, 11.
" expansion of, 3-7.
" heating effect of, 111.
glass, its rate of expansion, 4.
heat, its action on wood, 32.
" conduction and convection of, 7-11.
" latent, 18-20.
" loss of in furnaces, 114-116.
" radiation of, 11.
" sources, 2.
" specific, 16-18.
heating apparatus, PERKINS', 10.
" power of different fuels, 106-118.
HODGES' experiments on the distillation of peat, 59.
HUTCHINSON on the conducting power of building materials, 8.
hydrogen, its low pyrometrical effect, 110.
" excess of in different woods, 113.
" and carbon as combustibles, 25.
Irish Peat Company's Works, 60-62.
KANE's experiments on the distillation of peat, 58, 59.
LA CHABEAUSIERE's carbonizer, 41-43.
lamp-black, its high radiating power, 12.
latent caloric, 18-20.
LAVOISIER's method of determining the heat developed by combustion, 106.
lead and zinc, peculiarity in expansion, 4.
LESLIE's experiments on radiant heat, 12.
lignin, 30, 31.
lignite, 74, 110.
lignites, composition of, 76, 77.
liquids, conducting power of, 10.
" expansion of, 6, 7.
mechanical action a source of heat, 2.
mellers, or charcoal mounds, 36-39.
MELLONI's experiments on absorbent power of bodies for caloric, 13.
MELLONI's experiments on diathermous bodies, 14-16.
mercury, its rates of expansion, 4.
" its adaptation for thermometers, 7.
metals, conducting power of, 8.
MILNER's safes, 9.
mineral constituents of woods, 32.
MOLARD's application of the contraction of iron in cooling, 4.
Musical sounds by heated metals in contact, 2.

FUEL, continued.

nitrolin, 57.
PAPIN's digester, 23.
parrot coal, 75.
patent fuel, 97-102.
peat, 50-68.
" ash, yield of, 54.
" carbonization, 63-68.
" composition of, 52-54.
" compression, 56.
" density of, 51.
" heating effect, 110.
" origin of, 50, 51.
" preparation for house-fuel, 55.
" products of distillation, 57-60.
PERKINS' heating apparatus, 10.
phlogiston, 24.
PLAYFAIR and DE LA BECHE on the best coal for steam navigation, 117.
POUILLET's estimate of sun-heat, 2.
POWELL's colored rings, 3.
pyrometer, DANIELL's, 5.
radiation of heat, 11-13.
REAUMUR's thermometer, 3.
REECE's patent for distillation of peat, 58.
REID's ventilating apparatus, 11.
ROGERS' furnace for carbonizing heat, 66.
ROSE's fusible alloy, 7.
SCHWARTZ's carbonizer, 43.
solids, expansion of, 4-6.
specific heat, 16-18.
splint or hard coal, 75.
steam, 22, 23.
STONE's method of compressing peat, 56.
SULLIVAN's account of peat-distillation in Ireland, 58-63.
sun, heat of, 2.
thermometers, 3, 13.
thermopile, 14.
Torbanehill coal, 83-85.
TRELICH's coal-washing apparatus, 96.
ULLGREN's method of analysing fuels, 105.
ulmin, composition of, 57.
ventilation of buildings, 11.
VIGNOLES' patent for carbonizing peat, 67.
WARLICH's patent fuel, 99.
water, amount of, absorbed by charcoal, 48.
" amount of, in different woods, 26.
" its conducting power, 10.
" peculiarity in its expansion, 7, 11.
WELTER's theory of combustion, 24, 108.
WILL & VARRENTRAP's method of analysing fuels, 105.
WILLIAM's method of compressing peat, 56.
wood, action of heat upon, 32.
" amount of moisture in, 26.
" amount of combustible matter, 46.
" its conducting power, 9.
" constitution of, 25.
" density, 27, 28.
" distillation of, 45.
" heating effect, 110, 111.
" solid constituents of, 29-32.
" value of different kinds as fuel, 29.
" yield of, in charcoal, 46.
WYLAN's patent fuel, 98.
zinc and lead, peculiarity in their expansion, 4.
GAS—118-174.
acid, carbonic, 129.
" carbonic, 126.
" sulphurous, 127.
air, atmospheric, in coal-gas, 162, 163.
ammonia, 126.
amount produced from coal, 120.
analysis of coal-gas, 165.
anilin, 129.
animal matter, gas from, 151.
anthracin, 130.

GAS, continued.

aqueous vapor, 128.
 BASFORD'S method of purifying, 170.
 benzol, 124.
 bihydride of carbon, 122.
 bisulphide of carbon, 127.
 Boghead canal, gas from, 152-156.
 burners, 163, 164.
 " experiments on, 159-161.
 " ventilation of, 165.
 candles, their illuminating power compared with gas, 160-162.
 canal coal, produce of gas from, 132.
 " English, the best gas coal, 120.
 carbides of hydrogen, 122, 131.
 carbolic acid, 129.
 carbon, bihydride of, 122.
 " bisulphide of, 127, 162, 163.
 carbonaceous deposit, GRAFTON'S discovery, 139.
 carbonic acid, 126, 166.
 " oxide, 124.
 chrysen, 130.
 coal for gas, selection of, 130.
 " distillation of, 131, 132.
 " effects of water on, 130.
 " produce of gas from, 147-149.
 coal-gas, analysis of, 121, 165.
 " estimation of, 166-170.
 condenser, 139.
 cost of different means of illumination, 162.
 CROLL'S patent, 174.
 cumol, 129.
 cyanogen, 124, 125.
 distillation of coal, 131, 232.
 DUNDONALD first uses gas for illumination, 119.
 exhauster, 139.
 FRANKLAND & WARD'S apparatus, 169.
 gas-coal, choice of, 130.
 gas-holder, 144.
 governor, 144.
 heat from gas, 161.
 historical notice, 119.
 house-meter, 145, 146.
 hydrate of phenyl, 129.
 hydraulic main, 138.
 hydrocarbons, volatile, 124.
 hydrocarbon gas, 151-156.
 hydrogen, 121, 122.
 " carbides of, 122, 131.
 " sulphide of, 125, 162, 163.
 illuminating gas, nature of, 120.
 " power of gases, 149, 154, 156-162.
 illumination, relative cost of different means of, 162.
 leucolin, 129.
 lime purifiers, 141, 142.
 luminiferous constituents of coal-gas, 166.
 main, hydraulic, 138.
 manufacture of coal-gas, 133.
 meter for domestic use, 145, 146.
 " for stations, 143.
 MICHAEL'S improvements in manufacturing, 172-174.
 MURDOCH, the discoverer of the practical application of gas, 119.
 naphthalin, 129.
 nitrogen, 123.
 non-luminiferous constituents of coal-gas, 166.
 oil-gas, 151, 152.
 oily matters, 128.
 olefant gas, 123.
 paranaphthalin, 130.
 patents for purifying, *et cetera*, 170-174.
 phenyl, hydrate of, 129.
 picolin, 129.
 pipes from retorts to main, 137.
 POOLE'S patent for regulating the flow and pressure of gas, 171.
 produce from different coals, 147-149.
 purifiers, 140-142.
 purifying, BUSFORD'S method, 170.
 " CRISHOLM'S method, 171.
 pyren, 130.
 quinolin, 129.
 resin gas, 149, 150.
 retorts, 136, 137.
 retort-house, 133-136.
 scrubber, 139.
 soap-water, gas from, 152.
 station-meter, 143.
 sulphide of hydrogen, 125.
 sulphurous acid, 127.
 tell-tale, 143.
 toluol, 125.
 turf, gas from, 151.
 vapor, aqueous, 128.
 volatile hydrocarbons, 124.

GAS, continued.

water, its effects on coal, 130.
 water-gas, 151.
 WINSON'S patent for lighting with gas, 119.
 wood, gas from, 151.

GELATIN—174-183.

acids, their action on, 176.
 adulteration of isinglass, 180.
 alkalies, action of, on gelatin, 176.
 ARNEY'S patent, 178.
 BRAZILIAN isinglass, 179.
 cod sounds, 180.
 composition of, 177.
 " of isinglass, 180.
 COX'S patent, 178.
 East India isinglass, 180.
 glue, 181-183.
 isinglass, 178-181.
 leucin, 177.
 NELSON'S patent, 177.
 New York isinglass, 179.
 patents for preparing, 177, 178.
 preparation of, 174.
 properties, 175.
 " of glue, 182.
 " of isinglass, 180.
 ROPE'S patent, 178.
 Russian isinglass, 178.
 statistics, 183.
 sugar of gelatin, 177.
 SWINBORNE'S patent, 178.
 tannic acid, its combinations with gelatin, 176.
 tests for, 176.
 uses, 177.
 " of isinglass, 180.

GLASS—183-250.

acids, their action on, 198, 199.
 air, action of, 197.
 alkalies, action of, 198.
 alumina, 203.
 America, glass-making introduced, 137.
 annealing, 194, 200, 219.
 arsenic, 203.
 artificial gems, 240.
 aventurine, 243.
 baryta, 203.
 blowing-pipe, 207.
 Bohemian, 191, 211.
 Bologna phial, 194.
 BONTEMPS' optical glass, 237.
 bottle-glass, composition of, 191.
 " green, 208-210.
 " white, 211.
 bottle-moulds, 233, 234.
 brittleness of, 193.
 casting plate-glass, 224.
 champagne bottles, 211.
 CHANCE'S improvements in makingsheet-glass, 219, 221, 222.
 CHAPTAL'S experiments on volcanic products, 204.
 chemical constitution, 192.
 " properties of, 197.
 " glass, 211.
 colored glass, 238-243.
 coloring materials, 239.
 composition of, 189, 191, 192.
 " of flint-glass, 229.
 constituents, special effect of, 189, 190.
 crown-glass, English, 214-216.
 " foreign, 212-214.
 crystal, 228, 235.
 " composition of, 192.
 crystallization of, 194-197.
 cullet, 203.
 cutting and polishing flint-glass, 234.
 cuvettes, 213.
 cylinder-glass, 216-222.
 decoloring materials, 203.
 definition of, 184.
 deoxidising bodies, their action on glass, 197.
 devitrified glass, 194-197.
 DRAYTON'S process for silvering mirrors, 227.
 duties on, 247.
 enamel, composition of, 192.
 England, glass-making introduced, 187.
 English crown-glass, 214-216.
 engraving on, 235.
 etching on, 235, 236.
 FARTHING'S improved flattening-kiln, 220.
 faults in, 206.
 felspar, glass from, 204.
 filigree work, Venetian, 241.
 fining, 206.
 flashing and casing, 241.
 flint-glass, 228-235.
 " colored, 240.
 " composition of, 192.
 " furnace, 199.
 France, glass-making introduced, 187.
 frosted, Venetian, 242.
 FUCHS' stereochrome, 245.
 fuel for glass-furnaces, 205.
 furnaces, 199, 200.
 fusibility of, 193.
 gems, artificial, 240.
 glass-gall, composition of, 206.
 glass-house and furnaces, 199.
 glory-hole, 201.
 gravity, specific, 197.
 green bottle-glass, 208-210.
 grinding and polishing sheet-glass, 221.
 " plate-glass, 225-227.
 GUINAND'S optical glass, 237.
 HARTLEY'S improved flattening-kiln, 220.
 Hebrews, acquainted with glass, 184.
 Herculanum, glass utensils in, 185.
 historical notice, 184-189.
 hydrofluoric acid, its special action on glass, 199.
 iron, 203.
 lead, 203.
 leer, 200.
 lime, 203.
 manganese a decoloring agent, 203.
 manufacture of, 199.
 marver, 207.
 materials for glass-making, 202-205.
 medicinal glass, composition of, 191.
 melting the materials, 205.
 " and fining of flint-glass, 231.
 mille-flore or star-work, 242.
 mirrors, silvering, 227.
 mosaic in glass, 242.
 moulded Roman pillars, 234.
 moulding by pressure, 234.
 nature and composition of, 189, 191, 192.
 optical glass, 236-238.
 painting on, 188, 243.
 pipe for blowing, 207.
 plate-glass, 192, 222-223.
 PLINY'S account of its discovery, 181.
 pontil or ponty, 207.
 Portland vase, 185.
 potassa, 202.
 pots, 201.
 properties, chemical, 197.
 pucellas, 207.
 Roman glass manufactory, 185.
 RUPEE'S drops, 193.
 sandiver, composition of, 206.
 seed or blister, 206.
 silica, 202.
 sheet-glass, 216-222.
 silvering of mirrors, 227.
 soda, 202.
 soluble glass, 244-246.
 spring-tool, 207.
 spun glass, 244.
 staining, history of, 188.
 statistics, 246-250.
 stereochrome, FUCHS', 245.
 strass, composition of, 192.
 " and colored glass, 238-243.
 striae or waves, 206.
 tears in glass, 207.
 tools for working, 207.
 tube-drawing, 212.
 varieties of, commercial, 190.
 Venetian filigree-work, 241.
 " frosted glass, 242.
 Venetians, their skill in glass making, 187.
 VIRGIL'S mirror, 229.
 vitro-di-trino, 242.
 volcanic products, glass from, 204.
 water, its action on glass, 197.
 white glass, composition of, 191.
 " bottle-glass, 211.
 window-glass, 186, 192, 213.
 working-tools, 207.
 zinc optical glass, 238.

GLASS, continued.

GLYCERIN—250-252.
 analysis of, 252.
 composition, 250.
 glycol, 250.
 lypyl, 250.
 preparation and properties, 250, 251.

GOLD—252-310.
 abundance at great depths conjectured, 262.
 Africa, its gold regions, 258.
 alchemy, 254, 255.

GOLD, continued.

alloys, 287.
 " quantitative estimation of, 295.
 amalgamating machines, 275-279.
 amalgamation, known to the ancients, 258.
 America, its gold districts, 258.
 analysis, 298.
 aqua regia, 266.
 arsenical pyrites, 280.
 artificial, 293.
 Asia, gold mines in, 257, 264.
 assaying, 299-306.
 aurates, 294.
 Australia, gold exported from, 308.
 " gold diggings in, 259, 260.
 book-gilding, 291.
 Burgos lustre, 295.
 burnish-gilding, 290.
 California, 258, 259.
 " value of gold from, 308.
 carat, definition of, 287.
 cassius, purple of, 294.
 cementation, 286.
 chemical examination of ores, 267.
 chlorides of, 293.
 coinage of different countries, 309.
 compounds of, chemical, 293.
 consumption of gold and silver, 309.
 copper, testing for, 269.
 " pyrites, 263.
 cradle for gold-washing, 272.
 crushing the ore, 271.
 crystallized, 265.
 cupellation or refining, 283-285.
 " of the assay, 302.
 digging tools, 270.
 distillation of the mercury used for amalgamation, 279.
 electro-gilding, 293.
 electrum, 253.
 estimation, quantitative, of gold ores and alloys, 295.
 Europe, its gold mines, 256.
 examining auriferous districts, 262.
 fine washing, 275.
 flux for quartz or silica, 281.
 French standard gold, 288.
 fulminating, 294.
 furnaces for assaying, 300, 301.
 fusion of gold dust, 281.
 gilding, 290-293.
 gold-beating, 288-290.
 golden calf, theories on, 254.
 gold-sifter, 273.
 gravity, specific, estimation by, 295.
 grinding the ore, 272.
 hand-washing, 272.
 historical notice, 252-255.
 Hungarian mines, 257.
 ignorance of Biblical commentators, 254.
 ingot-mould, 300.
 iron pyrites, 263.
 " smelting with, 282.

glucose, 962.
hilum, 942.
history and sources, 939.
horse-chestnut, 960.
hydrochloric acid, its action on, 948.
Indian corn starch, 945, 959.
inulin, 939.
iodide of, 943, 949.
lichen starch, 939.
maize, 945, 959.
manufacture of, 950.
Martin's process, 951.
millet, 959.
oat starch, 944.
physical properties of, 939.
potato starch, 939, 946, 952-953.
properties of, 939-947.
rice starch, 945, 958.
rye starch, 944.
sago, 961.
sugar from, 963.
tapioca, 960.
tous-les-mois, 961.
wheat starch, 944.

STRONTIUM—964-965.

carbonate of strontia, 965.
chloride of strontium, 965.
nitrate of strontia, 965.
oxide of strontium, 964.
sulphate of strontia, 965.

SUGAR—965-1006.

analyses of French beets, 996.
baryta, sugarate of, 967.
beet-root, 996-999.
boiling points of sirup *in vacuo*, 983.
bone-black, revivification of, 980.
cane, cultivation of, 970.
cane-juice, constitution of, 973.
" extraction of, 974-976.
cane-sugar, 966.
carmelin, 970.
centrifugal machines, 995.
CHANTRELL's reviving kiln, 980.
charcoal filtration, 978.

SUGAR, continued.

clarifiers, 988.
composition of different kinds of, 966.
concentration of the juice, 982, 991.
consumption of, 1004.
crystallizing the sirup, 984.
cultivation of the cane, 970.
decoloration of cane juice, 978.
decomposition of cane juice, 1000.
DUMONT's filter, 978.
estimation of, 968.
evaporation of the juice, 982.
glucose, 968.
grape-sugar, 968.
historical notice, 965, 966.
imports, 1004.
impurities, 1001.
juice, decomposition of, 1000.
" evaporation of, 982.
" extraction of, 974-976.
lead, sugarate of, 967, 968.
lime, as purifying agent, 976.
" sugarates of, 967.
loss in manufacture, cause of, 1000.
mannite, 968.
maple, 999.
milk, sugar of, 968.
mill, interior of, 990-994.
" used in colonies, 987.
mosite, 968.
patent processes, 1002-1004.
PEYRON's filter, 979.
physiological effects, 1001.
polarized light, action on, 969.
potassa, sugarate of, 967.
precipitation of, 1001.
produce of the cane, 972.
properties of cane sugar, 967.
purification of the sirup, 976.
refinery, 993.
refining process, 986.
revivification of bone-black, 980.
sirup, purification of, 976.
" specific gravity of, 968, 969.
soda, sugarate of, 967.
sorbine, 968.
starch and wood, sugar of, 1000.
statistics, 1004-1006.
sugarates, 967.
tests of concentration, 983.
uses, 1001.
vacuum pans, 984.
varieties of, 966.

SULPHUR—1006-1018.

antichlor, 1016, 1017.
balsam of, 1007.
bisulphide of carbon, 1014.
chloride of, 1014.
combinations, 1018.
DUCLOS' process, 1010.
DYAR and CHISHOLME's patent for recovering sulphur from sulphurous acid, 1012.
extraction from its ores and salts, 1010.
flowers of, 1008.
GOSAGE's method of extracting sulphur from alkali waste, 1010, 1011.
hyposulphite of soda, 1015.
hyposulphurous acid, 1015.
iron pyrites, extraction from, 1010.
JACQUEMIN's method of producing sulphur from sulphate of lime, 1012.
LEE's process of extracting, 1010.
M'DOUGALL and RAWSON's process for reproducing sulphur from sulphide of hydrogen, 1011.
milk of, 1009.
native, 1006.
occurrence of, 1006.
oleum sulphuratum, 1007.
pentathionic acid, 1010.
precipitate, 1009.
properties, 1006, 1007.
purification, 1007-1009.
pyrites, extraction of sulphur from, 1010.
soda, hyposulphite of, 1015.
" sulphite of, 1017.
specific gravity of, 1007.

CHEMISTRY

THEORETICAL, PRACTICAL, AND ANALYTICAL,

AS APPLIED AND RELATING TO

THE ARTS AND MANUFACTURES.

There are qualities in the products of Nature yet undiscovered, and combinations in the powers of Art yet untried. It is the duty of every man to endeavor that something may be added, by his industry, to the hereditary aggregate of knowledge and happiness.—Dr. JOUSSON.

FUEL—NATURE AND PROPERTIES OF CALORIC.

FUEL.—*Combustible*, French; *Brennstoff*, German; *Fomes*, Latin.—The importance which must have been attached in every age, from the earliest period of human existence, to fire, and the necessity which has ever impelled mankind to provide it, not so much for purposes of luxury, as an absolute essential, to enable them to counteract the effects of climate and other external influences which affect the frame, are sufficient, apart from any other consideration, to impress every one with a sense of its usefulness. It is not in reference to these primary applications, however, that the full value of fire, or the extent of its influence, will be understood, but only when it is studied in connection with the various natural and artificial transformations of matter which it produces.

Nations, however rude or barbarous they might have been, always made use of fire: Firstly, as a means of preservation; Secondly, as a source of comfort or luxury; and lastly, as a destructive agent. The history of its application in relation to these three objects would offer a comprehensive view of the advance of civilization. Not only do the attributes of fire exert a gigantic influence in the various social requirements, but in the most minute as well as the most elaborate changes which take place in nature. Heat and light, indeed, seem to be the life-giving principles of the material world, and are not less essential to man in subduing matter to his service.

Among the material sources of heat, all the substances chemically termed *combustible*, such as carbon, sulphur, phosphorus, potassium, iron, *et cetera*, may be regarded as particular kinds of fuel, although the name is usually restricted to organic products of ligneous origin, such as woody matters, coal, peat, and the like.

As the consideration of fuel is intimately associated with heat, and as this is a subject of great practical importance, it will be necessary to enter into somewhat

lengthened details in regard to the nature of caloric—the term applied to the substance or cause of heat, in contradistinction to the sensation which it produces. This theoretical inquiry is essential to a full understanding of various processes and instruments mentioned in the present work, and more especially is it indispensable to a complete elucidation of the nature and action of fuel; or, in other words, of those substances employed to generate that principle which constitutes the great agent, not only in impelling machinery, but in most manufacturing operations. The Editor will, therefore, make no apology for entering here at considerable length into a preliminary exposition of the nature of heat or caloric.

NATURE AND PROPERTIES OF CALORIC.—Of the three imponderables—caloric, light, and electricity—caloric is that which produces the sensation of heat or warmth in animal bodies. It exists, however, in considerable quantities, even when it cannot be distinguished by this test.

Substances communicate a warm sensation when their contained heat exceeds that of the part of the body which touches them; and they are said to be cold when the heat of the latter is greater. Hence it is evident that heat and cold are merely relative terms, and do not indicate the actual amount of caloric which is contained in any body. This can be readily proved by exposing the two hands to unequal degrees of temperature, and then bringing them in contact with a body containing an intermediate quantity; the heated hand will experience the sensation of cold, and the other of heat; that is to say, the same substance will communicate the sensation of heat or cold, according to the temperature of the part of the body touching it.

Caloric is self-repulsive, and eminently destroys cohesion, because it induces the particles of matter to separate to a greater or less distance, according to the

amount of it which combines with them—thus producing what is termed *expansion* or *dilatation*. It pervades and penetrates all bodies, however compact they may be, and seems to be in constant intercommunication between them, more especially if they are possessed of it in unequal quantities. In its passage from any one body to surrounding objects, it emanates in direct lines with a velocity hitherto undetermined, but supposed to be equal to that of light. Its intensity, also, diminishes in the ratio of the square of the distance from the heated body. Thus, if at the distance of one foot from the source of heat the effect be accounted unity, at two feet it will be only one-fourth as much, at three only one-ninth, and so on. Heat may be conveyed from one body to another in three ways: firstly, it may pass from one particle to another when the substances are in contact; secondly, it may be emitted in direct lines to a distance; and, thirdly, it may be received after passing through another body which offers little resistance to it. In the first of these cases, it is said to be *conducted*; in the second, *radiated*; and in the third, *transmitted*. In many of its properties it resembles light—more especially in the facility with which it is reflected and refracted. The phenomena of dew, wind, frost, snow, and other atmospheric changes, are consequences of the unequal amount of caloric combined with water.

Sources of Caloric.—Among the acknowledged sources of heat—namely, the sun, electricity, chemical and mechanical action—some enumerate vital action; but this may be regarded as included in the preceding list, for its operations may be referred to the united effects of chemical and mechanical action.

The heat of the sun has been approximately estimated by POUILLET, as between 2662° and 3202° Fahr. When the rays of this luminary are concentrated either by lenses or reflectors, a great amount of caloric may be brought to operate on bodies at a considerable distance. BUFFON ignited a board of tarred beech with forty reflectors, at a distance of sixty-six feet; with the power of one hundred and twenty-eight mirrors he set on fire a tarred pine plank, which was one hundred and fifty feet distant. Pieces of coin and other metallic matters were readily melted by this means.

Electricity supplies a heat so intense as to be capable of fusing and even volatilizing matters which, under ordinary circumstances, resist the action of the hottest furnace. Indeed, by galvanism, the highest temperature hitherto obtained has been produced.

Chemical action is, next to the sun's rays, the commonest and most useful source of heat, and the methods of generating it in this manner are various; but that which is best known and most frequently resorted to is combustion. By *combustion* is usually understood that change which a body undergoes on being ignited in the air, and by which light and heat are evolved, whilst the substance itself disappears. Chemically considered, however, combustion is the effect of the union of two or more elements, whereby heat is always disengaged, though light is not a necessary consequent in every instance. Thus, in numerous chemical combinations, considerable quantities of caloric are set free, unattended with luminousness. Animal or vital heat is generated principally by the chemical changes which

the food as well as the components of the body are constantly undergoing; and the movements of the members contribute to its more rapid production.

Finally, mechanical action, either by percussion or friction, is capable of disengaging heat from bodies in large quantities. For instance, if a bar of iron be struck with a hammer, a certain amount of caloric will be evolved at every stroke; and by vigorously continuing the action the bar may be made red-hot. But after a rod of metal which has been rendered incandescent by this means has once cooled, no amount of mechanical force is afterwards sufficient to bring it again to a glow, unless it be heated in the fire and allowed to cool. This is owing to the circumstance, that the metal cannot secrete in its condensed state as much latent heat as would be necessary to raise its temperature when further compressed; for the evolution of heat by percussion appears to depend upon the compression of the particles of the body struck. BERTHOLLET measured the amount of caloric emitted from the strokes of a coining-press; he found that, at the first stroke, it gave off 17.3° , at the second 7.5° , and at the third only 1.9° .

Friction is another mechanical means of producing or developing caloric. Instances of this are familiar to engineers, and workers in metal who are engaged in boring, filing, *et cetera*. Even the rubbing of one piece of ice against another may be made to produce an evolution of heat sufficient to melt both, and this will take place more or less quickly according to the amount of force applied in the friction. Count RUMFORD ascertained that the heat liberated in boring a piece of cannon seven and a half inches in diameter, the instrument making thirty revolutions per minute under a pressure of ten thousand pounds, was sufficient to boil eighteen pounds of water in two hours and a half. If a bar of steel be forcibly struck against a piece of flint or other hard body, the caloric which is set free will be sufficient to cause the combustion of the particles of the metal which are disengaged, and which are seen to fly off in sparks.

Expansive Action of Caloric.—The effects of caloric upon matter are various; but that which is most important, and which will require to be considered first, as affording a convenient measure of its intensity, is its *expansive action*. The distribution of matter into aeriform, liquid, and solid bodies depends on this principle. Many bodies possess the quality of uniting with heat and retaining it to such an extent, that they remain permanently liquid or gaseous, whilst other compounds, having less of the same principle, are solid at ordinary temperatures. In rendering solid bodies aeriform and liquid, the self-repulsive action of the heat overcomes the cohesive force with which the particles were held together, and separates them to a certain distance, dependent upon the amount of caloric absorbed. When a bar of brass strongly heated is placed upon another one of a different kind, but which is an imperfect conductor, for instance lead, the repulsive action of heat will be shown by the evolution of sound. This happens in consequence of caloric being communicated by the heated metal to the lead in contact with it, but not being immediately conducted to other particles of the

latter metal, repulsion follows, and the hot body is thrown out of close union; descending, however, by the force of gravity, it again comes in contact with the lead, or nearly so. This contact is immediately broken off, and again renewed, the movement thus continuing in rapid succession till the brass cools. The vibration gives rise to musical sounds. BADEN POWELL ingeniously measured the force of the self-repulsion of heat by means of colored rings. A flat and convex glass plate were strongly pressed together, and the colored rings formed by the refraction of light from the thin stratum of air between, afforded him the means of estimating the repulsive force; for when heat was applied to the lower plate, the rings altered and closed in towards the centre, showing that the glass plates receded from one another. Now, as each of the annular colors has a certain determinate thickness, it is evident that the degree of repulsion may be ascertained from the narrowing which occurs in the breadth of the rings as the temperature rises.

The expansion or dilatation produced in bodies by heat is a familiar phenomenon. Very great difference exists, however, as to the extent to which divers substances are affected by the same amount of heat. In such compounds as are permanently gaseous, no opposition is offered to the distending power of the combined caloric, and the result is, that these dilate in a regular and uniform ratio, no matter how hot or cold they may be when the caloric is communicated. It is different with solids and liquids, in which the resistance offered by the varying force of cohesion must first be overcome before any discernible repulsion of the particles succeeds. Where this opposing force is great, it is evident that a much larger amount of heat will be required to distend them. Hence the difference in the rate of expansion of bodies produced by this agency.

The Thermometer.—The thermometer, or heat-measurer, is constructed upon the principle of the expansion of bodies by caloric. It consists, in its common form, of a glass tube terminating in a bulb containing mercury or some other fluid, which fills the bulb and part of the tube; and the rise or fall of the fluid in the tube, according as the mass of it in the bulb expands or contracts, indicates the changes of temperature in the surrounding medium. This most indispensable instrument was not known previous to the sixteenth century, and, at its first introduction by the Florentine academicians, its indications were not very trustworthy. At first, the change of the amount of caloric was estimated by the expansion of air; but this, although in common with other aeriform fluids more regular than liquids or solids in its alteration of volume by increased or diminished temperatures, offered so much inconvenience in the wide extent of its range, besides being largely affected by the varying pressure of the atmosphere, that it was found necessary to substitute another fluid. Various liquids, such as linseed oil and spirit of wine, were tried with good effect; but, for general purposes, mercury was found to be the most suitable. The range between its points of solidification and ebullition is greater than that of any other known fluid; it is also a good conductor of heat, and is, consequently, rapid in

its indications, and sensitive to sudden changes of temperature. It is true that it experiences, like other fluids, as will be explained afterwards, a constantly increasing rate of expansion as the temperature rises, but between the freezing and boiling points of water this irregularity is so minute, as to be really of little or no moment even in very accurate investigations; indeed, the slight deviation which takes place is nearly compensated by the glass, which expands in much the same proportion as mercury.

There are three varieties of this instrument, differing merely in the notation. FAHRENHEIT, whose thermometer is generally used in this country, fixed the zero of his scale at the temperature of a mixture of snow and salt, and divided the interval between this and the boiling point of water into two hundred and twelve equal parts or degrees, so that on this scale water freezes at 32° , and there are 180° between its freezing and boiling points. CELSIUS, in constructing his modification of the thermometer, assumed as the zero of his scale the freezing point of water, and, proceeding on the decimal principle, divided the interval between this and the boiling point into one hundred equal parts, so that on this scale the point of ebullition is indicated by 100° . Hence, his instrument, which is used extensively on the Continent, has been called the Centigrade. In REAUMUR's scale, as in the Centigrade, the freezing point is the zero; but the distance between the freezing and boiling points is in REAUMUR's divided into 80 equal parts, instead of 100, so that on this scale the boiling point of water is at 80° . In each of these thermometers the degrees of temperature under the zero are indicated by the sign *minus*. Thus, -15° Fahr. indicates fifteen degrees of that scale below the temperature of a mixture of snow and salt; while the same notation on the Centigrade or Reaumur scale signifies a temperature fifteen degrees of the one or the other of these scales below the freezing point of water.

By very simple formulæ, the degrees of any of these thermometers may be converted into the equivalent of the others. The same distance is divided in the three thermometers into 180° in Fahrenheit's, 80° in Reaumur's, and 100° in the Centigrade. Now, dividing by twenty, it will be seen that these numbers are in the ratio of 9 : 4 : 5; or, in other words, nine degrees of Fahrenheit's scale are equivalent to four degrees of Reaumur's, and five of the Centigrade. Hence, indicating the respective thermometers by the initials F., R., C., the length of a degree in each will be as follows:—

$$1^{\circ} \text{ F.} : 1^{\circ} \text{ R.} : 1^{\circ} \text{ C.} :: \frac{1}{9} : \frac{1}{4} : \frac{1}{5}$$

But the temperature is measured by the number of divisions contained in equal portions of the stem of the respective thermometers. Now, the zero point of Fahrenheit's is 32° below freezing point. If, therefore, $F.^{\circ} - 32$, $R.^{\circ}$, $C.^{\circ}$, indicate the same temperature on each of the three thermometers, one has the proportion:—

$$F.^{\circ} - 32 : C.^{\circ} : R.^{\circ} :: 9 : 5 : 4$$

whence result the following equations for converting one scale into another:—

$$\begin{aligned}
 4 \text{ (F.}^\circ\text{--32)} &= 9 \text{ R.}^\circ \\
 5 \text{ (F.}^\circ\text{--32)} &= 9 \text{ C.}^\circ \\
 5 \text{ R.}^\circ &= 4 \text{ C.}^\circ \\
 &\text{or,} \\
 \frac{1}{9} \text{ (F.}^\circ\text{--32)} &= \frac{1}{4} \text{ R.}^\circ = \frac{1}{5} \text{ C.}^\circ
 \end{aligned}$$

The divisions principally used are those of Fahrenheit and the Centigrade, and the equations for passing from the indications of the Centigrade to those of Fahrenheit, and *vice versa*, are—

$$\begin{aligned}
 \text{F.}^\circ &= 32 + \frac{9}{5} \text{ C.}^\circ \\
 \text{C.}^\circ &= \frac{5}{9} (\text{F.}^\circ - 32)
 \end{aligned}$$

that is, add thirty-two to nine-fifths of the number indicated on the Centigrade, and the result is the number which would be indicated by Fahrenheit; subtract thirty-two from the number indicated by Fahrenheit, and five-ninths of the remainder is the number which would be indicated by the Centigrade.

When very low temperatures, under -40° Fahr., have to be estimated, a mercurial thermometer cannot be employed, since this metal solidifies at that point; in such cases, alcohol colored by some matter is used in the bulb of the instrument. On the other hand, mercury boils at about 600° Fahr., and, therefore, when very high temperatures are to be estimated, a different instrument, termed the pyrometer, is employed, which will be described in the sequel.

Whatever be the form of thermometer, it is evident that the indications are merely relative, and do not express the actual amount of caloric which a substance contains. The use of the thermometer, therefore, is merely to indicate the sensible heat, or that which is capable of being radiated or communicated from one material to another; and for this purpose it is of most important application in various branches of the arts and manufactures, serving for the guidance of the operatives in numerous processes, to the success of which it is absolutely indispensable.

Expansion of Solids.—The rate of expansion in solid bodies is greatly dependent on their state of aggregation; hence it will be evident that the same amount of caloric will operate differently on different solids, but the effect is more visible in the metals than upon other solid non-metallic substances.

The following table exhibits the rate of expansion of a few solids when heated from 32° to 212° FAHR.

TABLE OF EXPANSION FROM 32° TO 212° FAHR.

Name.	Expansion in length.	Do. in bulk.	Authorities.
Zinc, cast,	1 in 323		
„ sheet,	1 „ 340	1 in 113	Smeaton.
Lead,	1 „ 351	1 „ 117	
Tin,	1 „ 516	1 „ 172	
Silver,	1 „ 524	1 „ 175	Lavoisier
Brass,	1 „ 536	1 „ 179	and
Copper,	1 „ 582	1 „ 194	Laplace.
Gold,	1 „ 682	1 „ 227	
Bismuth,	1 „ 712	1 „ 239	Smeaton.
Iron,	1 „ 846	1 „ 282	{ Dulong and
Antimony,	1 „ 923	1 „ 307	Petit.
Tempered steel, . . .	1 „ 926	1 „ 309	Smeaton.
Palladium,	1 „ 1000	1 „ 333	Lav. and Lap.
Platinum,	1 „ 1131	1 „ 377	Wollaston.
Glass without lead, 1 „	1148	1 „ 382	{ Dulong and
Flint glass,	1 „ 1248	1 „ 416	Petit.
			Lav. and Lap.

From the foregoing results it is evident that the expansion in bulk is about three times as great as the

linear expansion; or, in other words, by multiplying the latter by three, the product will approach closely to the increase in bulk. It must be observed, however, that the expansion is not uniform for equal increments of temperature, for all bodies tend to expand more as the heat reaches a high degree. This is especially the case with metals; hence it is that mercurial thermometers are not well adapted for measuring degrees of temperature much higher than that of boiling water, owing to the increase of the metal at high heats being greater than at low. The rates of expansion in mercury from 32° to 572° are—one in 55.08 between the freezing and boiling points of water; one in 54.61 between the latter and 392° ; and one in 54.01 between this and 572° .

The extent to which glass expands when heated within the same range is given in the table annexed:—

Temperature by air thermometer.	Mean absolute dilatation of glass for each degree.	Temperature by thermometer made of glass.
From 32° to 212°	$\frac{1}{55.08}$	212°
„ 32° to 392°	$\frac{1}{54.61}$	415.8°
„ 32° to 572°	$\frac{1}{54.01}$	667.2°

Most solids return to their original volume when they have parted with the caloric which caused the distention of their particles; some, however, are incapable of doing so, and are permanently elongated or enlarged every time they are subjected to the influence of a high temperature. Such is the case, more especially, with zinc and lead—the particles of which, in sliding over each other, are supposed to possess an amount of adhesive friction which prevents their retraction to the full extent they had expanded.

The expansion or contraction of bodies, occasioned by an increase or diminution of temperature, takes place with enormous force. The amount of this has been estimated by BARLOW, who found that a bar of metal, of one square inch section, is elongated one ten-thousandth of its length by receiving an addition to its temperature of 16° ; to produce the same effect mechanically would require a ton weight to be suspended from it, or the application of an equivalent force. A careful attention to this subject is indispensable in the sciences of engineering, horology, *et cetera*. It has been found that within the usual range of the variation of the temperature of England throughout the year, a bar of wrought-iron, ten inches long, will expand about two hundredths of an inch. Were both its extremities secured firmly to other objects, this change would exert a force, tending towards their removal, of fifty tons to the square inch; hence it is to be observed that where beams of wood are to be replaced by iron ones, care should be taken that room for occasional expansion should be allowed them, otherwise very ruinous consequences might result. From the numerous and varied uses to which iron is now applied, this is a subject of very great importance. An accurate calculation must be made, and the structure so formed, as that the expansion or contraction of the metal shall not endanger its stability.

A very ingenious application of the power obtained by the enormous force of the contraction of metals was made by MOLARD, to secure the Museum of Arts and

Manufactures in Paris, by restoring the walls, which were giving way outward owing to the weight of the roof. His method was to insert bars of iron horizontally through the building, so as to protrude a little from the walls at each side. Heat was then applied by lamps suspended over the whole length of the bars, and the metal expanded to some extent, after which iron nuts were firmly screwed on the bars at both ends, and tightened to the wall as much as possible; the heat being now removed, the metal began to contract, and in doing so, it drew the nuts closer together, which had the effect of bringing the walls nearer to the perpendicular. By a repetition of the heating of the bars, and again tightening the nuts or plates, the bulges were entirely removed, and the walls were restored to their vertical position. In many of the ordinary arts of life, a similar advantage has been taken of the effect of heat upon bodies to render peculiar service; the wheel-wright, by heating the tire and fitting it on in an expanded state, and then allowing it to contract, insures the firmness and durability of the wheel; the cooper, in like manner,

heats the hoops of his casks, *et cetera*, when fitting them in their proper place, so that when they cool they may bind the staves more firmly; and the boiler-maker uses red-hot rivets as well for facilitating their plating, as for binding the sheets of metal more tightly by their subsequent contraction on cooling.

The sudden application of heat to many bodies is productive of fracture, owing to a partial expansion of the part heated, while the part not so affected refuses to yield. This is frequently seen in glass and cast-iron plates. Indeed, the most delicate part of the glass-maker's business, as will be seen in a future article, is the annealing; or, in other words, the exposure of the goods to a gradual cooling, which renders them less liable to crack when exposed to sudden changes of temperature.

A tabular statement of the rate of expansion of a few of the metals is subjoined, with a comparative view of the results when the temperature is measured with the air thermometer, and with one constructed of the metals under experiment:—

Temperature by air thermometer.	Mean dilatation of iron for each degree.	Temperature by iron rod thermometer.	Mean dilatation of copper for each degree.	Temperature by copper thermometer.	Mean dilatation of platinum for each degree.	Temperature by platinum thermometer.
212°	50160	212°	34120	212°	57380	212°
572°	40678	702°5	31800	623°8	55340	592°9

In estimating the temperature at high degrees by a mercurial thermometer, the observations made as to the rise of the metal indicate only the difference between the expansion of the glass and that of the metal, which, in ordinary cases, is supposed to be uniform; but owing to the increased expansion which the mercury experiences at a high temperature, 572° on the air thermometer corresponds with 586° on the mercurial one. The same temperature estimated by glass alone would be indicated by 667°, thus showing that the dilatation of the glass counteracts the expansion of the fluid metal. Considerable difference will be observed in the table between the indication of the air thermometer and that which is found by measuring the expansion of bars of metal; so that at high temperatures, which liquids and gaseous bodies cannot be employed to measure, the true indication of heat, as compared with the air thermometer, is somewhat difficult to ascertain. A further obstacle stands in the way, inasmuch as the rate of expansion in metals and most solid bodies is unequal. M. BREQUET contrived to overcome this by constructing a solid thermometer, composed of a compound ribbon of three metals—gold, platinum, and silver—rolled out very thin and coiled spirally. The upper end of these was fixed, and the lower one attached to an index which described an arc, as the helix twisted or untwisted, by the greater expansion or contraction of the silver band over the platinum one. By graduating the range of the index, and finding the value of the indications by comparing them with those of a standard thermometer, the instrument was completed.

The Pyrometer.—When the temperature is very high, such as that at which the more infusible metals melt, or of a reverberatory or wind furnace, the common thermometer is unavailable, and other instruments for estimating the heat have been invented, which are called *pyro-*

mers. Of these, DANIELL'S register pyrometer, represented in Fig. 1, is the most accurate. It consists of two parts, namely, the register and the scale. The register

Fig. 1.

is a solid bar of black-lead, A, highly baked, in the axis of which is drilled a hole reaching to within half an inch of the end; into this hole a bar of iron, or of platinum, *aa*, is introduced. A cylindrical piece of porcelain, *c*, sufficiently long to project a short

distance from the extremity, is placed end-wise upon the iron, and the former is bound to the bar by a band of platinum, *d*, passing round both, and tightened, if necessary, by a wedge of porcelain, *e*. When this instrument is exposed to a very high heat, the whole increases in bulk, in proportion to its intensity; but the rate of expansion of the metal and of its casing being unequal, the porcelain cylinder, *cc*, will be protruded to the extent of the difference.

To measure the length of the protruded portion, the scale is applied. This consists of two brass rules, *f*, *g*, joined together by screws, to form a right

angle, and fitting exactly upon the sides of the register. The plate, *h*, rests on the shoulder of the bar, *A*, formed for the platinum band. At the extremity of the rule nearest this, an arm, *D*, movable upon its centre, *i*, is fixed; and at the other an arc of a circle, *E*, graduated into degrees and thirds of degrees. Upon the latter, at *h'*, is another lighter arm, *C*, carrying upon the end of its longer limb a nonius, *H*, which moves upon the face of the arc, *E*, and subdivides the graduations into minutes. The other end of this arm protrudes beyond the centre of motion, and carries a steel knife-edged bar, which fits into the notch cut for it in the termination of the index.

The index bar is pressed firmly down upon the metal encased in the black-lead, and securely fixed there by the wedge and band of platinum; the bar is

then nicely adjusted in the angle formed by the two rules of the scale; the plate, *h*, firmly held against the shoulder, and the knife edge, *m*, resting in the notch in the index bar; the position of the latter is now noted on the scale, and after the register has been heated and allowed to cool, the scale is again applied and the result observed—the difference is the value of the expansion of the metal bar. By comparing this with the indications given by a mercurial thermometer between any two points, say that of the freezing and boiling of water, an expression in degrees of Fahrenheit's scale may be given to any degree of artificial heat measurable by the instrument.

DANIELL, with this apparatus, obtained the following results, in which the expansion is shown at three stages:—

1,000,000 parts at 62°.	At 212°.	At 662°.	At fusing point.
Black-lead ware,.....	1,000,244	1,000,703	
Wedgwood ware,.....	1,000,735	1,002,995	
Platinum,.....	1,000,735	1,002,995	1,009,926 maximum, but not fused.
Iron—wrought,.....	1,000,984	1,004,483	1,018,378 to the fusing point of cast-iron.
Iron—cast,.....	1,000,893	1,003,943	1,016,389
Gold,.....	1,001,025	1,004,238	
Copper,.....	1,001,430	1,006,347	1,024,376
Silver,.....	1,001,626	1,006,886	1,020,640
Zinc,.....	1,002,480	1,008,527	1,012,621
Lead,.....	1,002,323	—	1,000,972
Tin,.....	1,001,472	—	1,003,798

Expansion of Liquids.—In liquids, the expansion produced by heat is much more marked than in solids; they also differ among themselves in the amount of expansion produced by equal increments of heat. The most volatile liquids, or those of which the boiling point is low, are found to be the most expansible under the influence of an increase of caloric, as may be observed from the appended table, showing the comparative increase in volume of several liquids when heated from 32° to 212°:—

Water,.....	0.0466	Dalton.
Saturated solution of chloride of sodium,.....	0.0500	"
Concentrated sulphuric acid,.....	0.0600	"
Hydrochloric acid, specific gravity 1.137.....	0.0600	"
Nitric acid, specific gravity 1.40.....	0.1100	"
Alcohol, specific gravity 0.817.....	0.1100	"
Ether,.....	0.0700	"
Oil of turpentine,.....	0.0700	"
Fat oil,.....	0.0800	"
Mercury,.....	0.02000	"
".....	0.01887	Cavendish.

Mercury,.....	0.01848	Lavoisier and Laplace
".....	0.01818	Hallstrom.
".....	0.01801	Shuckburgh.
".....	0.01800	Petit and Dulong.
".....	0.01786	Deluc.
".....	0.01665	Roy.

A difference in the seething point of liquids, however, does not always show a corresponding variation in their expansion, as was long ago proved by LAVOISIER with regard to alcohol and bisulphide of carbon, two liquids differing in their boiling points by 57°, yet the rate of expansion is the same in both for each increase of an equal number of degrees of heat, reckoned from their respective boiling points. PIERRE found similar results in his researches upon liquids of analogous composition, such as the bromides and iodides of ethyl and methyl. This relation, however, does not appear between some of the isomeric bodies examined, as may be seen from the annexed table, showing the

CONTRACTION FROM THE BOILING POINTS:—

Name of Liquid.	Boiling point Fahr.	Temperature equidis- tant from the boiling point of each group.	Interval between the preceding tem- peratures.	Volume at boiling point.	Volume at equidistant temperatures.
FIRST GROUP.					
Sulphide of carbon,.....	118.22°	22.72°	140.94°	1	0.913099
Alcohol,.....	172.94	32	140.94	1	0.914452
Wood spirit,.....	151.34	10.4	140.94	1	0.905819
SECOND GROUP.					
Bromide of ethyl,.....	105.26	32	73.26	1	0.944375
Bromide of methyl,.....	55.4	17.86	73.26	1	0.944575
THIRD GROUP.					
Iodide of ethyl,.....	158	32	126	1	0.918704
Iodide of methyl,.....	110.84	15.16	126	1	0.916643
FOURTH GROUP.					
Formiate of oxide of ethyl,.....	127.22	20.12	107.1	1	0.910223
Formiate of oxide of methyl,.....	139.10	32	107.1	1	0.918750

With reference to the second law which governs the expansion of liquids—namely, that they are progressively more expansible at higher than at lower temperatures—it is to be remarked, that in this respect considerable difference exists between different liquids; and in mercury the higher expansion at higher temperatures is less than in any other fluid body. Hence, it is better adapted than any of them for the construction of thermometers. The expansion which takes place in each of the substances enumerated in the following table, between the freezing and boiling points of water at the ordinary pressure, is represented by one hundred parts, and the increase which equal increments of heat produce above 212° is proportionally estimated:—

Dulong and Petit.					
Air.	Mercury.	Platinum.	Copper.	Iron.	Glass.
0 .. 0	0 .. 0	0 .. 0	0 .. 0	0 .. 0	0 .. 0
100 .. 100	100 .. 100	100 .. 100	100 .. 100	100 .. 100	100 .. 100
150 .. 151.3

" "	122° to 99.5°	" "	9.3 "
" "	99.5° to 77°	" "	7.7 "
" "	77° to 54.5°	" "	3.9 "
" "	54.5° to 32°	" "	0.2 "

The dilatation of water, when reduced in temperature below 39.4°, serves a purpose of the greatest consequence in the economy of nature—namely, in preventing the transmission of cold beyond the surface of the water in very rigorous seasons, and preserving the chief bulk of the fluid at such a temperature as is congenial to the life of the animals that inhabit it. The fusible alloy of ROSE possesses properties in some respects analogous to water. This substance increases in bulk till it reaches about 111°, after which it contracts when its temperature is being raised from this to 156°, the point of its greatest density, and at which its bulk is less than when at the freezing point of water; after this, however, it continues to expand till it reaches its fusing point at 201°.

Expansion of Gases.—The third class of bodies to be considered in relation to the expansive force of heat, are gases. All these being at ordinary temperatures in a state in which the atomical aggregation manifests a highly repulsive tendency, it is evident that they will be influenced to a greater extent by caloric than either of the foregoing classes. A remarkable coincidence or uniformity, however, is found to exist among the different members of this class; and, knowing the rate of expansion of one when combined with a certain amount of caloric, the same may be taken as the expansive power of the other permanent gases and elastic vapors when subjected to an equal increase of temperature. By former investigations, this was found to amount to about three hundred and seventy-five parts in a thousand of air, when heated from the freezing to the boiling point of water; later researches, however, have shown that the true expansion of air within these limits is three hundred and sixty-six parts, or $\frac{1}{491.2}$ of the whole for each degree of Fahrenheit's scale.

Dulong and Petit.				
Air.	Mercury.	Platinum.	Copper.	Iron.
250 .. 255.1				
300 .. 314.15		311.6 ..	328.8 ..	372.6 ..
350 .. 360				352.9

Water, within the range of its solidifying point and that at which it becomes an elastic vapor, is subject to very great irregularities. The general law, as before expressed, is, that heat exerts an expansive force upon all bodies; but, within a certain range, water becomes an exception. If this liquid be taken in the solid state, or at the temperature of 32°, before it has solidified, and caloric be communicated to it, instead of expanding, it actually contracts till it marks about 39.4°, at which it has attained its greatest density. Above this, it expands in the same ratio that the contraction took place for an equal number of degrees, but beyond that point it obeys the general law.

COUNT RUMFORD found the contraction of water for every 22.5° from the boiling to the freezing temperatures to be as follows, namely:—

Below the freezing and above the boiling point of water, the expansion is in the same ratio. A volume of gas measuring four hundred and ninety-one parts at 32° Fahr. expands, for every degree of heat additional, one part; so that at 60°—that is, with an increase of 28° of the thermometric scale—the volume becomes five hundred and nineteen parts. This ratio continues as long as the temperature rises, so that when the whole is heated to 523° = 32° + 491°, or in other words, is raised through as many degrees as there are original divisions in the bulk of the liquid, the volume will be doubled; and in proportion as multiples of this increase of temperature are applied, so will the air dilate to three, four, or more times its bulk. It was found, however, by MAGNUS and REGNAULT that the operation of this law is not perfectly uniform, especially with reference to the easily liquefied gases, which are more expansible than air when exposed to equal increments of heat, as the following table will show:—

Names of Gases.	Expansion upon one volume from 32° to 212°.	
	Magnus.	Regnault.
Atmospheric air,	0.366508	0.36650
Hydrogen,	0.365659	0.36678
Carbonic acid,	0.369087	0.36896
Sulphurous acid,	0.385618	0.36696
Nitrogen,	—	0.36682
Nitrous oxide,	—	0.36763
Carbonic oxide,	—	0.36667
Cyanogen,	—	0.36821
Hydrochloric acid,	—	0.36812

A sensible increase in the rate of expansion is also found when the gas is submitted to pressure, compared with that which takes place when it is in a rarefied state.

CONDUCTION AND CONVECTION OF HEAT.—Another point of great importance is the comparative

facility with which heat is conveyed or conducted through different bodies. When caloric comes in contact with solids or liquids, it enters into them and traverses from molecule to molecule, till it has permeated the whole. This property of heat, although by many supposed to be due to radiation, owing to the particles of matter not being in absolute contact, is, however, generally acknowledged to be due to a distinct action—that of conduction.

Different substances vary considerably in regard to the freedom with which caloric passes through them—that is to say, in their conducting power; and many very useful applications have been made of this property in the arts and sciences. It is upon this principle that nature protects every species of animal and vegetal life against the injurious influence of meteorological changes. The differences observed in the physical appearance of man and of other races of animals, according to their position on the globe, are ordered in conformity with the laws which regulate the conduction of heat; and the means adopted by various nations for shielding their persons from the opposite extremes of heat and cold, as also the covering of every indigenous species of living being, no matter of what class or kind, are all most admirably suited to the state and condition in which they live. The colored cuticle of the African, whose existence is ordained under a burning sun, is not less requisite for radiating or allowing a free passage for the heat he has to endure, than is the white skin of the European to prevent the sudden ingress and egress of caloric to or from the body. Not only does the natural state give proof of this wise disposition in the human species: it is still more manifest in the lower orders of creation, which have not like man the reasoning power that enables him to provide for the exigencies of his condition; hence they are usually defended by a non-conducting coat of fur or feathers, protecting them from sudden transitions of temperature.

Dense and heavy substances are generally good conductors; light and porous bodies have this property only imperfectly. This may be proved by taking metallic rods, to which small balls of wax are attached at different distances, and introducing one end of them into the flame of a candle. As the heat proceeds from one particle of the metal to another, its progress may be measured by the falling off of the balls successively, owing to the wax being melted by the heat. But if cylinders of wood, glass, or wax be heated in a similar manner, a different result will be observed, owing to the latter being bad conductors of caloric. A practical application of this fact is seen in metallic instruments intended to be used while hot; these are invariably furnished with handles of some badly-conducting material—such as wood or glass—to protect the hand from being scorched.

DESPRETZ instituted a series of experiments for determining the conducting power of metals. His method was to drill holes, at the distance of 3·93 inches apart, in bars of the metal of an equal and determinate thickness; into these holes thermometers were inserted, and the ends of the metals then applied to a heating medium. Caloric was allowed to traverse

the bars as long as the thermometers continued to indicate an increase in the temperature. The observations made in this way furnished the annexed numbers:—

Gold,.....	1000·0
Silver,.....	973·0
Copper,.....	898·2
Iron,.....	374·3
Zinc,.....	363·0
Tin,.....	303·9
Lead,.....	179·6
Marble,.....	23·6
Porcelain,.....	12·2
Fire-clay,.....	11·4

Platinum is a singular exception to the general rule above stated; for, unlike silver, copper, or such other dense bodies, a wire of this metal may be held in the hand and heated to redness at one end, even when only a few inches in length. Glass, although a substance of moderate density, is likewise a bad conductor. The conducting power of a body is much diminished by its being pulverized; thus, metallic filings are worse conductors than bars of the same material; pounded glass and sawdust are also inferior in this respect to solid rods of glass or wood. Charcoal conducts heat very feebly; as also sand, and a number of other bodies, all of which on this account are of importance in cottage architecture, and for other purposes, in which it is desirable to provide against sudden changes of temperature.

The following are the results which Mr. HUTCHINSON obtained in his researches on the conducting powers of building materials. The substances are arranged in the order in which they resist the passage of heat, the best non-conductors being placed first:—

Name of substance.	Conducting power referred to that of slate, equal 100.
Plaster and sand,.....	18·70
Keene's cement,.....	19·01
Plaster of Paris,.....	20·26
Roman cement,.....	20·88
Beech wood,.....	22·44
Lath and plaster,.....	25·55
Fir wood,.....	27·61
Oak wood,.....	33·66
Asphalte,.....	45·19
Chalk—soft,.....	56·38
Napoleon marble,.....	58·27
Stock brick,.....	60·14
Bath stone,.....	61·08
Fire brick,.....	61·70
Painswick stone, H.P.,.....	71·36
Malm brick,.....	72·92
Portland stone,.....	75·10
Lunelle marble,.....	75·41
Bolsover stone, H.P.,.....	76·35
Norfal stone, H.P.,.....	95·36
Slate,.....	100·00
Yorkshire flag,.....	110·94
Lead,.....	521·34

Besides the use which is made of the property of non-conduction in architecture, there are other departments of the arts and manufactures in which it subserves important purposes. Thus it is applied with good effect in constructing fireproof edifices or apartments, and in the manufacture of chests and boxes intended to preserve valuable property, legal documents, *et cetera*, from the destructive effects of conflagration.

In the latter case, this is effected by interposing some solid body which is a bad conductor of heat between the interior lining and the exterior frame of the chest. The well-known safes of MILNER and SON, of Liverpool, are constructed in this way. The inner chamber is made of stout sheet-iron, firmly secured by riveted bolts to the exterior one, which, by its strength, is calculated to resist fire, and any external violence, either intentional or accidental, to which it is liable. The intermediate chamber is filled with a composition which can scarcely be excelled as a non-conducting material, whilst, at the same time, is heat-absorbing

Fig. 2.

power, or, in other words, its quality of rendering heat latent or insensible, is very great. From repeated test-

Fig. 3.

ings, at some of which the Editor attended, these articles have been proved capable of withstanding a twenty-four hours' fire of intense heat without allowing the contents to be injured in the least. Fig. 2 is a front view, and Fig. 3 a section of one of these safes. In Fig. 3, the chamber containing the non-conducting material is shown. At one time this consisted almost entirely of

VOL. II.

water, and hermetically sealed with a fusible alloy. When the heat reached them, the plug of metal by melting allowed the water to flow out, thus moistening the ingredients, and arresting the passage of the caloric. If the fire were prolonged, the moisture would be disseminated in vapor in the inner chamber where the valuables were deposited, and thus would secure them still more perfectly against combustion. The tubes, however, were found troublesome and expensive, and improvements of a simpler nature adopted. According to the specification of Mr. MILNER, the ingredients now used are quartz, crystallized carbonate of soda or alum, and the dust of hard woods, all of which are blended in such proportions as that twenty-five per cent. of the whole shall consist of moisture, which is capable of being expelled on the application of heat. The water in this case is exclusively derived from the salts—the carbonate of soda containing sixty-two and the alum fifty-five per cent. of water, which is separated slowly even with the application of a very high temperature.

The same principle is brought into requisition when the design is to preserve the heat in rooms and prevent it from escaping. In this case, the object is accomplished by constructing double doors and windows: thus enclosing a partition of air, which is a very imperfect conductor of caloric, and, therefore, the heat of the chamber is retained. In a similar manner, fireproof chambers may be made, having, in connection with the space between the double walls, a means for supplying cold air to occupy the place of that which must pass off as the increased temperature expands it. Unless such provision be made, the pressure which the increased tension of the vapor acquires as the heat increases would be apt to burst the walls.

On similar principles great attention is required in selecting the materials employed in the construction of furnaces. To prevent the escape of the caloric, and thus to economise fuel, the hearth and walls of the furnace are invariably compounded of some non-conducting substance, as Stourbridge clay or powdered brick, mixed with a large quantity of powdered charcoal or coke. For the same reason, boilers are imbedded in bricks or clay, and in many boilers the fire is literally enclosed within them, that none of the heat may be lost, but that all may be rendered available for raising the temperature of the water.

SERAMONT examined the conducting power of crystalline bodies, and proved that, in such as do not belong to the regular system, power varies in different directions according to the inclination of the optic axis of the crystal. DE LA RIVE and DECANOLLE have, in like manner, shown that the conducting power of wood is different according to the direction in which the heat is transmitted, being greatest in the course of the grain or fibre, and least across it. TYNDALL has established the same fact by showing that caloric much more readily traverses from the surface of a log of wood to the centre, than it does in a direction parallel to the annular layers of ligneous matter. In woods, also, as in metals, their conducting power appears to vary with their specific gravity, being

B

least in the lightest kinds; this, however, requires corroboration. Textile fibres which are manufactured into articles of clothing are very bad conductors; but their actual conducting power cannot be exactly ascertained, in consequence of the air which is contained in their pores.

Liquids in general are bad conductors of heat; it was formerly asserted, indeed, by some chemists, that water is an absolute non-conductor; it has been proved, however, that liquids conduct caloric in some measure, subject to the same laws as solids, although, as regards water and other such mobile liquids, very feebly.

The following experiment, among many which might be adduced, will illustrate the weak conducting power of water:—

Let the mouth of a bottomless glass jar, A, be closed by a perforated cork, through which the stem of an air thermometer, E, passes. Invert the jar, and pour into it cold water till nearly half-filled; on the surface of this cold liquid, place a cork disc, and then introduce a quantity of warm water colored either red or blue, to distinguish the two portions of liquid. The disc may now be cautiously removed, and the hot water will remain in a distinct layer upon the other. If the heat were conducted through the cold medium, it would act upon the air thermometer by causing the expansion of the enclosed air, and the expulsion of a proportionate quantity of the liquid from the stem; but no such effect is observed. If the cold water be now drawn off from the bottom by means of a siphon, D, it will still be found that no rise of temperature is indicated by the instrument, till the colored liquid comes in contact with the bulb, when the confined air will be expanded, and the tinged liquor in the stem ejected into the vessel into which the thermometer dips. From this it is evident that the conducting power of water is very feeble, and so with other similar mobile liquids. If, however, mercury be substituted for the cold water, and the warm water poured upon it, the effect upon the thermometer is instantaneous. This proves that fluidity is not the cause of the non-conduction of heat by water, and other similar bodies, but that it depends to a certain extent on the nature of the substance itself.

Moreover, the effect observed is very different when, instead of applying caloric at the upper surface, it is communicated to the under part, or to the bottom of the vessel in which the liquid is contained. In this case, the particles in immediate contact with the heat-giving body acquire a portion of caloric, and are expanded. This, by rendering them lighter than the surrounding ones, causes them to ascend; fresh particles succeed, and these rise in a similar manner. Currents are thus determined in the liquid, and

caloric is readily communicated to the whole mass. This, however, is not a case of conduction from particle to particle; neither is it due to radiation, which will be afterwards explained; but is the effect of *convection*—that is to say, the actual conveyance or distribution of the heated portion throughout the mass.

Very great benefits are derivable from this property of fluids. It has been

advantageously applied in the ventilation of buildings, the hot air rising to the top and escaping, while cool air is injected. It is upon this principle also that PERKINS'S apparatus for the heating of dwellings is constructed. This is represented in its simplest form in Fig. 5; it essentially consists of an iron pipe one inch in exterior diameter, and half an inch in the bore. This being filled with water and distributed throughout the building, a portion of it is heated in a furnace, and a current is thus

established through its entire length. The caloric acquired by the water in its passage through the heated portion of the pipe, is given off by radiation in performing the rest of the circuit, till it returns to be reheated. The several coils, A A A, may represent as many apartments, each embracing a considerable length of pipe; the coil, B C, which is generally about one-sixth of the whole length, and which is represented on a larger scale in Fig. 6, receives the heat of the furnace. The course

Fig. 5.

Fig. 6.

of the water from this portion is through the pipe, a a, which rises till it reaches to the top of the building; here it branches off into several conduits to traverse the different parts of the edifice, all reuniting in the

pipe, B, before returning to the furnace. Water is introduced at the open end, D, which is kept tightly plugged while the apparatus is in action; a space, E, is provided in connection with the pipe at the top of the building, to admit of room for the expansion of the heated liquid, and thus prevent the bursting of pipes: its capacity is about one-fifth or one-sixth of the whole.

Apart from the consideration of the useful purposes to which the convection of heat is applied in the arts, a far more important end is served by it in the economy of nature. During the frosts of winter, the process of cooling goes on downward from the surface of the earth and water. The colder water at the top becoming condensed, and consequently heavier than that beneath, sinks and gives place to the latter; this goes on as long as the atmosphere remains at a low temperature, till the water is reduced to its maximum density, a point which it attains at $39^{\circ}4'$. It is a remarkable circumstance, and forms a singular exception to a general law, that water when cooled to this point begins to expand, and consequently remains at the surface. When cooled to 32° it freezes, and during its conversion into ice it experiences a still further expansion, so that the ice, instead of sinking to the bottom, and there accumulating in dense masses, floats on the surface till melted—one of the most wonderful provisions for the preservation of life in the whole economy of nature.

In their mode of conducting heat, gases resemble liquids; that is to say, their power of actual conduction is inappreciable; but by their property of convection, currents are instituted by which the heat is disseminated throughout the mass. To observe this, it is only requisite to hold the hand first at the side of a lighted candle, and then above it, the distance in both cases being equal; it will be perceived that, in the first position, little heat is received, whilst in the second the increase of temperature is immediately obvious, the greater portion of the heat being carried off in the ascending current; which, in gases, is more active than in liquids, owing to their power of expansion being so much greater. The application of these currents of heated air is of great practical importance in the ventilation of dwellings and public buildings. Indeed, in every species of human habitation, provided with a fire-place and chimney, the latter operates as a ventilating apparatus. The heat derived from the combustion of fuel in the grate or on the hearth, dilates the super-imposed atmosphere, and causes its ascent in the shaft, while an influx of air to the fire supplies its place. The transmission of smoke and warm air through the chimney soon raises its temperature, and, on this account, the heat which is received from the fire is retained by the vapor till it passes out at the top. The force of the current or *draught* thus formed will be in proportion to the greater expansion of a column of air of the height of the chimney, than that of an equal column externally. Common air, like other gases, increases one five-hundredth of its bulk for each degree of temperature which it acquires; hence, by ascertaining the internal temperature and height of

the chimney, the force of the ascending atmospheric column may be calculated. When it happens that the apartment is very close, and does not admit sufficient air to supply a stream from beneath, it enters at the top of the shaft, and causes a *back draught*. In such cases the chimney is said to smoke, and the remedy usually applied is to open the door or window, so as to admit sufficient air to maintain the current. To avoid smoke, care should be taken in hanging the doors, *et cetera*, that space be allowed for the influx of air, so as to prevent its entrance from above. It is a well-known fact, that in a heated apartment the warmer portion of air rises to the ceiling, and the colder stratum remains underneath; hence it is obvious, that to maintain a proper state of ventilation, apertures must be provided in or near the ceiling, whereby the warm gases may escape. This, however, will prove ineffectual, unless provision be made for the entrance of a corresponding volume of air at or near the floor, to supply the place of that expelled. In large buildings, where the heat eliminated from fires would be ineffectual towards warming them, heated air is used in nearly the same way as the water in PERKINS'S method, only that the hot air is distributed in the various apartments through gratings in the floorings or side walls. Dr. REID'S apparatus for ventilating St. George's Hall, Liverpool, operates in this way; and several other large enclosures and churches throughout the kingdom are heated on the same principle. The phenomena of winds and oceanic currents are all referrible to the same cause; and, as in the case of ventilating apparatus, so on the large scale of the globe, the streams or currents which are induced by differences of temperature tend to equalize the amount of heat which is received from the sun, to distribute it more uniformly over sea and land, and thus to modify the intensity of cold and heat in climates exposed to opposite extremes of temperature.

RADIATION OF HEAT.—On the whole, it may be laid down as a general law, that air, the gases, water, and fluids generally, with the exception of mercury, are bad conductors of caloric, notwithstanding that it is distributed readily by them in the manner already explained. Although, however, it is the natural tendency of convection to operate upwards, yet, if the hand or the bulb of a sensitive thermometer be placed at some distance beneath a warm body, or on either side of it, an increase of heat will be indicated. From this it is evident, that though the permanent gases and the atmosphere do not sensibly conduct caloric, yet, in common with liquids and other transparent bodies, they permit its passage without being themselves appreciably affected by it. All the caloric received by the earth from the sun—the amount of which, to each acre in the latitude of London, is calculated by FARADAY to be equivalent to that which is generated by the combustion of sixty sacks of coal—thus travels through the intermediate space of ninety-five millions of miles, without sensibly affecting the temperature of the atmosphere, or that of the subtle medium beyond it. When heat emanates from any body in this way, it is said to be radiated from it, and the imponderable itself is denominated *radiant heat*. Thus, if a bar of heated

metal be suspended in a room for some time, the excess of caloric contained in it will pass off in all directions, and the metal ultimately indicates only the same temperature as the surrounding objects. During the cooling, the heat passes off at all points of the body in direct lines as from a centre—hence the term *radiated*. To prove that convection and radiation are distinct processes, and that the latter is not a consequence of the former, all that is necessary is to expose a heated body in the vacuum of an air-pump, in which case it will be observed that the emission of caloric is much quicker even than if it were allowed to cool in contact with the air.

In simple language, the rate of cooling expresses the radiating power; and LESLIE ascertained that the radiating power of bodies was more influenced by the state of their surface than by the nature of the material. A bright tin globe filled with water at a certain temperature was allowed to cool, and the time being carefully noted, it was found that the contents of the vessel cooled half way to the temperature of the room, in one hundred and fifty-six minutes. When the same experiment was repeated with the surface of the globe coated with lamp-black, it was observed that the mercury in the thermometer fell through the same space as it did in the first experiment in eighty-one minutes: thus showing, that by the alteration of the surface the radiating power was doubled. Count RUMFORD corroborated this observation by another experiment. Taking two brass cylinders of equal size and capacity, and investing one of them tightly with linen, while the other was left bare, he filled the two with boiling water, and allowed them to cool. During this process, he observed that the coated cylinder lost 10° of its original temperature in thirty-six minutes and a half, while the other required fifty-five minutes to pass through an equal range. Hence may be deduced the important practical inference, that liquids are best kept warm in highly polished vessels, and that it is an error to wrap them round with cloths or other coverings, which radiate the heat more rapidly than polished metals.

By following the method of LESLIE and Count RUMFORD in the foregoing experiments, namely, coating the heated surface with various materials, and observing the time required in cooling, or, as will be presently noticed, by concentrating the rays radiated from a certain extent of surface, and ascertaining their intensity by their action upon a delicate thermometer, the comparative radiating power of different bodies may be ascertained. By this method it has been found that lamp-black is superior in radiating power to any other substance hitherto submitted to experiment, and that if this be represented by 100

Writing paper will be	98
Resin	96
Sealing wax	95
Crown glass	90
Indian ink	88
Ice	85
Isinglass and red lead	80
Plumbago	75
Tarnished lead	45
Polished lead	19
“ tin plate, gold, silver, copper	12

From this table it will be seen that lamp-black irra-

diates five times as much of the caloric of boiling water as clean lead, and eight times more than bright tin. The general low radiating power of the metals is increased if these be allowed to tarnish, as exhibited in the case of lead in the preceding table. Smoothness of surface, however, does not always act in relation to other bodies as it does in metals, for glass and porcelain, although their surface is smooth, always radiate very powerfully. When the actual radiating surface is metallic, it is not affected in a sensible manner by the substance under it; thus glass, coated with gold leaf or tinfoil, possesses the radiating power of the superimposed metals.

In general, the rapidity of cooling of any body depends upon the excess of its temperature over that of the external air; the hotter it is, the more freely does it give out caloric in a given time, and, as its temperature sinks, the longer is it in parting with the excess. DULONG and PETIT found that the rate of cooling differs according to the nature of the atmosphere surrounding the heated bodies; they also observed, whilst making experiments upon bodies in vacuo, that if they acquired heat in an arithmetical ratio, the same would be radiated in a geometrical one.

Radiant heat is absorbed, reflected, or transmitted, according to the nature of the body on which it impinges; and the absorption, reflection, or transmission is in every case governed by peculiar laws. Polished metallic surfaces reflect the greater portion of the heat which falls upon them; and the incidental and reflected rays are in the same plane, and make equal angles with the reflecting surface. If two concave metallic mirrors be placed directly opposite to each other at some distance, and a lighted candle be fixed in the focus of one of them, the rays of heat received by the latter will be found reflected to the opposite mirror, where, instead of being absorbed, they will be further reflected and concentrated in the focus of this one; and, if a delicate differential thermometer be placed at this point, the quantity of heat thus concentrated may be registered. Such was the method adopted by LESLIE, MELLONI, and others, in their researches upon heat, as shown in the annexed engraving, Fig. 7. In this case the reflectors, if thoroughly

Fig. 7.

polished, do not acquire a perceptible increase of temperature, nor indeed do any of those bodies which throw off by reflection the rays of heat incident upon them. It is only when the reflection is incomplete, either from the nature of the body or the want of a sufficient polish, that heating of the mirrors takes place. If in the above experiment a reflector of glass were

used instead of one of metal, only a very small portion of the calorific rays would be reflected, the greater part being absorbed by the disk, which in consequence would readily indicate a higher temperature; but by coating the surface of the glass with gold leaf or bright tinfoil, it will then become a polished metallic mirror, capable of powerfully reflecting the calorific rays. By experiments such as these, LESLIE demonstrated that the reflecting power of a body is chiefly dependent on the nature and condition of its surface, and that those qualities which are adverse to radiation are such as promote reflection. Bright smooth metallic surfaces, such as polished silver, brass, or steel, which are strongly retentive of their own heat, are little prone to receive it from other sources, but cause its reflection in the same plane, and at an angle equal to that at which it strikes the surface. It is to this circumstance that the Dutch oven and meat screen owe their great efficacy in culinary processes.

The *differential thermometer* or *thermoscope*, to which allusion has been made in the preceding passage, and which is represented in the last figure in the focus of the left-hand reflector, is shown on a larger scale in Fig. 8, and consists of two bulbs, A and B, containing

air, united by a tube twice bent at right angles, in which there is a little colored sulphuric acid. This is essentially an air thermometer, from which the atmospheric pressure is excluded. When heat is applied to one of the bulbs, the air within it expands, and draws the fluid towards the other, when either its depression or elevation, showing the amount of the expansion, may be read off on the scale. It is evident that this instrument cannot be employed to indicate general changes of temperature in the surrounding medium. It is not affected by such changes,

which act equally on both bulbs; but when one of these is exposed to any source of heat which does not affect the other, as when it is placed in the focus of a reflector, the *difference* of temperature between the two bulbs is immediately and very sensibly indicated by the recession of the fluid from the heated towards the cold bulb. The *thermopile*, an instrument still more sensitive to slight changes of temperature, will be described immediately.

MELLONI performed a number of experiments with the view of ascertaining the comparative absorbent

power of certain bodies for caloric. He employed a variety of heat sources of different degrees of intensity, and fixed the ball of a thermoscope coated with lamp-black at such a distance from each, that the liquid contained in it recorded the same degree of temperature in every instance. The distance being marked, the ball was removed and coated with other substances instead of lamp-black, and then successively exposed as before to the action of the heat radiated from different sources. The results showed a remarkable variation, according to the source of the caloric. Thus, when the ball was coated with white-lead and exposed to the rays from the flame of an oil lamp, it indicated only 53; but when red-hot platinum wire was substituted for the flame of the lamp, it was found to be 56; with a copper plate, it indicated 89; and, when exposed to a canister of boiling water, it registered 100. In each of the preceding cases, however, the thermoscope when blackened exhibited 100. The subjoined tabulated results, showing the relative absorbability of different kinds of heat, were obtained in this manner:—

Thermoscope coated with	Naked flame from oil lamp.	Incandescent platinum.	Copper at 750°.	Canister of water at 212°.
Lamp-black, ...	100	100	100	100
White-lead, ...	53	56	89	100
Isinglass, ...	52	54	84	91
Indian ink, ...	96	95	87	85
Shell-lac, ...	43	47	70	72
Polished metal, ...	14	13.5	13	13

With regard to the heating of bodies by radiation, KNOBLAUCH has shown that the effect produced when the radiated heat is *intensified* is totally independent of the temperature of the source, and is determined only by the nature of the absorbing bodies, which receive certain rays more readily than others. This was proved by coating one side of a sheet of metal with lamp-black, one half of the reverse being covered with carmine, and the other with black paper, and exposing the latter alternately to the action of an argand lamp, and a metal cylinder raised to 212°, while the side covered with lamp-black was turned towards the thermopile. With this arrangement the following results were obtained:—

Sources of heat.	Direct radiation.	Carmine.	Interposed Black paper.
Argand lamp,	35	9.50	10.75
" "	50	13.75	15.25
Cylinder heated to 212°, ...	35	10.87	10.12
" "	50	15.62	14.00

To determine how far the thickness of bodies affected their heating by radiation, he used a metal plate coated with layers of varnish:—

Sources of Heat.	Direct Radiation.	METALLIC PLATE										
		Naked.	Covered with									
			Layers of Varnish.				Layers of Black Lac.				Layers White Lead.	
			1.	2.	4.	8.	Thin.	Thick.	Thicker.	Thickest.	Thin.	Thick.
Argand lamp,.....	35°	6.50°	8.25°	8.25°	8.25°	8.25°	7.12°	8.25°	8.62°	9. 5°	7.25°	8.00°
“ “	60°	10.50°	14.50°	15.12°	15.62°	15.75°	14.50°	16.25°	17.37°	18.12°	16.12°	18.50°
Metal cylinder heated to 212°,	35°	6.50°	9.00°	9.25°	9.50°	9.50°	9.12°	9.87°	11.62°	12.00°	8.75°	9.62°
“ “	60°	10.50°	17.50°	17.50°	20.12°	20.75°	18.62°	20.25°	21.37°	20.17°	17.00°	19.50°

From these results it appears that the substances employed are more strongly heated in proportion as their thickness is greater, within certain limits. MELLONI and LESLIE arrived at a different conclusion, in consequence of having used plates of such thickness that only a small proportion of the heat absorbed could penetrate to the side which was turned towards the thermoscope; KNOBLAUCH, on the contrary, employed media, the thickness of which was not too great to allow each successive layer to be heated, and thus to act upon the metallic surface.

The Thermopile.—MELLONI found that caloric was transmitted by many bodies which were impervious to light, and these he termed *diathermous* or *heat-transmitting*, in contradistinction to *diaphanous* or *transparent* bodies. In conducting his experiments on this subject, he employed, in connection with a very delicate galvanometer, an instrument which he termed a thermopile. This consisted of a number of pairs of bars of bismuth and antimony joined together, and so enclosed in

Fig. 9.

a cylinder—see Fig. 9—that by turning one end of the latter towards the region whence the heat is radiated, it would fall upon the alternate points of junction of the bars of metal, and excite, as is well known, a current of electricity, the intensity of which is in proportion to the amount of heat received. By wires con-

necting both ends, x and y , of this battery with the galvanometer, the electricity was measured; and thus was obtained a ready and delicate method of estimating the amount of heat transmitted. Fig. 10 shows this arrangement, in which the pile is introduced. Both ends of the bars are blackened with soot, in order that the absorption of the rays of heat falling on them may be the more complete. By means of screens, a and b , the pile is preserved from the effects of currents of air; b has a conical shape, and is intended to concentrate the rays of heat when very feeble on the end of the pile. The pile is firmly bound, as represented at p , and fixed to a sliding stand in a perfectly horizontal position. x and y are bars in connection with the opposite ends of those of the pile, to which the wires g and h are screwed at one end, the other being in connection with the helice of coated wire that serves to act upon the galvanometer at m and n . The galvanometer is composed of a carefully selected and well magnetized pair of needles, bound together with fine copper wire, as seen in Fig. 11, and freely suspended in the middle of a glass cylinder, c , by a single fibre of silk which is attached to a ball, f , by turning which the needle may be raised or lowered at will. The helice, or multiplier, in the midst of which the needles are suspended, is constructed by winding

Fig. 11.

Fig. 10.

coated copper wire round a metal frame in forty layers, and properly isolated. Both the cylinder and multiplier are fixed to a table, so that when the needle hangs freely from f , it will rest in the centre of the closely divided circle, pointing to zero in the plane of the mag-

netic meridian. When the pile and multiplier are connected, the least change of temperature that may

affect the ends of the compound metals deflects the needle, and the amount of this deflection may be noted on the divided circle. When working with this instrument, the first deviation of the needle must be carefully distinguished from the proper angle of deflection—*id est*, from the angle which it makes with the magnetic meridian, when unaffected by any electrical currents. If the equilibrium of the galvanometer is disturbed by a stream of electricity, it returns from the point to which it has been deflected, with a certain degree of velocity, which causes it to go beyond zero; it will oscillate thus for some time before the stationary line is attained. To avoid the delay which these oscillations would occasion, MELLONI ascertained by experiments the ratio between the first and final deflection—*id est*, he determined how large the final deflection is that corresponds to the original one. The knowledge of this relation offers great advantages, inasmuch as each experiment lasts only ten or twelve seconds, whereas, if the operator had to wait till the needle became stationary, several minutes would be required.

If the principle of the apparatus comes to be considered, it will be evident that the relation which exists between the difference of temperature of the soldering points of the pile and the deflection of the needle cannot be ascertained in an absolute manner. To give the deflection a definite value as to the amount of caloric, MELLONI had to determine—after establishing the fact, that the strength of the electric stream from a pile of bismuth and antimony is proportional to the difference of temperature of the soldering points—the relation of the deviation of the needle to the strength of the stream. For this purpose, he placed at either end of the pile a constant source of heat—such as a LOCATELLI'S lamp—at such a distance, that when working alone at one end it caused a deflection of about 40° to the right, and, when placed at the other, the deflection marked 35° to the left side; but, when the sources of heat were permitted to operate on both ends at once, the deflection to the right marked 15° . From this behavior it was inferred that the difference between 40° and 35° corresponded with 15° counted from 0° . By operating in this way, it may easily be understood how, by changing these experiments, a table may be constructed, the first column of which expresses the observed deflection, and the second the corresponding number of degrees which would be arrived at if the deviation were proportional to the strength of the stream, and the action of the latter on the needle were not the weaker the more the latter is deflected. With the apparatus employed by MELLONI, the numbers on both columns up to 20° were equal—that is to say, till 20° the deflection of the needle is proportioned to the strength of the stream; but with the observed deflection, 25, 30, 35, 40, and 45° , correspond the value 27, 35, 47, 62, and 83° of the second column. A stream, therefore, that produces a deviation of 40° is 62 times stronger than another that causes only a variation of one degree. MELLONI so arranged his experiments that the deflections were always less than 30° .

To return to the manner of working the apparatus: if the body emitting rays of heat be fixed in the

focus of a reflector that impels the rays of heat in a horizontal line with the pile, and one of the ends of the latter be exposed to them, the effect upon the needle will, upon the principles already laid down, be indicative of the quantity of radiated heat. When different sources of caloric are thus presented in succession, the register of the deflection of the galvanometer will show the difference of radiation.

Transmission of Heat through Thin Plates.—The bodies employed by MELLONI were a LOCATELLI'S lamp, fixed as at A in Fig. 10; a coil of platinum kept at incandescence by the flame of alcohol, as seen in Fig. 12; a blackened copper foil fixed to a stand, and heated with a spirit lamp to 752° , as represented in Fig. 13; and a brass canister filled with water kept at 212° , as shown in Fig. 14. One or other

Fig. 12.

Fig. 13.

Fig. 14.

of these was placed on a movable support, as at A, behind the perforated screen, B, the rays being concentrated when necessary by the reflector at A, and received at a certain distance from this upon the thermoscope. The sensitiveness of the latter was proved by placing a double screen of polished copper, D, between it and the source of heat, so as to intercept all the caloric rays, and observing the deflection of the needle of the galvanometer in C, when the screen was removed. The elevation of temperature produced by the direct action of the radiating body being thus known, the substance to be examined was then introduced in the place of the screen, as at E. By observing the difference of temperature as indicated by the needle now, and comparing it with the effect produced without the screen, the proportion of heat transmitted by any interposed body was at once ascertained. By this method, MELLONI found that plates of rock-salt of great transparency, and varying in thickness from one-twelfth of an inch to two or three inches, transmitted ninety-two out of every hundred rays of heat which fell upon them, no matter from what source derived. As the remainder of the rays were found to be reflected from both surfaces of the plate, it may hence be concluded that what the colorless plate of glass is to rays of light, the plate of rock-salt is to those of heat. Sometimes the caloric rays which pass through one body are intercepted by a plate of another body, or by another plate of the same. In experimenting upon this, MELLONI found that the caloric which has passed through one plate of glass, becomes less subject to absorption in passing through a second and a third plate of the same material. Thus, of one thousand rays of heat from an oil lamp,

four hundred and fifty-one were intercepted in passing through four plates of equal thickness, and—

Of these the first plate intercepted	381
“ the second “	43
“ the third “	18
“ the fourth “	9
	451

It was found by DELAROCHE that the higher the temperature of the source of heat, the greater in proportion to the whole is the quantity which passes through a plate or screen of glass. He observed that from a body heated to 182° only one-fortieth of the whole permeated, whereas when the temperature was 346° the one-sixteenth passed through, and when the heat was raised to 960° Fahr. as much as one-fourth of the whole amount of heat was transmitted. To show the independence of diathermacy and translucency, MELLONI took a blackened ball of copper heated to 400° Fahr., and placing it midway between the blackened bulbs of two thermoscopes so that they might receive an equal amount of heat, noted the effect; then fixing between the ball and the instruments for measuring the heat plates of rock-salt and glass of equal thickness, it was quickly observed that the temperature of the bulb behind the former was much more elevated than the other—thus showing that more heat passed through it than through the glass one, although in transparency they were equal. In liquids this independence is still more manifest. Thus, out of one hundred rays that fell from an argand lamp on each of four fluids equally transparent—namely, water, oil of turpentine, ether, and sulphuric acid—the number of rays of heat transmitted were:—

Water	11
Sulphuric acid	17
Ether	21
Oil of turpentine	31

The following is a tabulated statement of some of the results ascertained by MELLONI on the subject of the transmission of heat through various bodies of equal thickness:—

Name of the interposed substance. Common thickness 0.102 inch.	Transmission of 100 rays of heat from			
	Naked oil flame.	Red-hot platinum.	Copper at 730° F.	Copper at 212° F.
Rock salt, transparent and colorless,	92	92	92	92
Sicilian sulphur, yellow,	74	77	60	54
Fluor spar, limpid,	72	69	42	33
Rock crystal, cloudy,	65	65	65	65
Beryl,	54	23	13	0
Flint glass,	67	—	—	—
Plate glass,	39	24	6	0
Iceland spar,	39	28	6	0
Rock crystal, limpid,	38	28	6	0
“ brownish,	37	28	6	0
Tourmaline, dark green,	18	6	3	0
Citric acid,	11	2	0	0
Alum,	9	2	0	0
Sugar candy, colorless,	8	1	0	0
Fluor spar,	8	6	4	3
Ice, transparent and colorless,	6	0	0	0

Similar experiments being performed with liquids contained in glass, the stratum being 0.362 inch in thickness, and the source of heat being in each case

flame from an argand oil-lamp, the annexed results were obtained:—

Bisulphide of carbon,	63
Bichloride of sulphur, red-brown,	63
Terchloride of phosphorus,	62
Essence of turpentine,	31
Colza oil, yellowish,	30
Olive oil, greenish,	30
Ether,	21
Sulphuric acid, colorless,	17
“ brown,	17
Nitric acid,	15
Alcohol,	15
Distilled water,	11

The fact that bodies which are pervious to light do not maintain the same relation to heat, is best exemplified by sulphate of copper, which permits the passage of blue light abundantly, but absolutely intercepts caloric. On the contrary, the opaque glass which is used for polarizing mirrors, allows the thermal rays to pass, but quite intercepts the light; and smoked rock-salt and black mica act in a similar way. Radiated heat is not only transmitted, but refracted in the same manner as light. This is proved by the well-known property of convex lenses or *burning glasses*, which concentrate not only the light, but the rays of heat, in the focus. Caloric further resembles light in apparently consisting of rays which possess different degrees of refrangibility, as may be proved by subjecting a beam of light to the action of a transparent prism of rock-salt, and examining the spectrum so obtained by means of a delicate thermometer. In this case it will be found that the heat varies at different parts of the spectrum; and experiment has shown that when the rays of the sun are operated upon, the most part of the rays of heat are less refrangible than even the red light; the maximum temperature being found at some distance below the extreme red. The refrangibility of the rays varies with the source of heat; the higher the temperature the greater is the refraction. For example, the rays of heat emitted from an argand lamp are refracted all over the spectrum, but the maximum intensity is about the middle; from ignited platinum the maximum falls nearer to the red; from copper heated to 750°, nearer still; and so on till the temperature of the source cools to 212°, when it is found to emit scarcely any of the more refrangible rays.

SPECIFIC HEAT.—Bodies have different capacities for heat; or, in other words, the application of the same amount of caloric will elevate the temperature of divers substances unequally. This capacity for caloric, varying in different bodies, is termed their *specific heat*. If a certain weight of water, at the ordinary temperature of the atmosphere, be mixed with an equal quantity of this liquid raised to a higher degree, the mixture will indicate a mean between these extremes; but if another liquid, such as oil or mercury, be added, instead of the second portion of water, a great difference will be observed. When a measure of water at 60° Fahr. is agitated with as much mercury at 140°, the compound, instead of marking 100° as in the preceding case, will indicate only 86.6°. Again, if mercury at 40° be added to an equal bulk of water at 156°, the heat of the latter is reduced by 3.7°, which, being absorbed by the fluid metal, raises it to 152.3°, so that

each degree which the water indicates by the instrument has the effect of 30·35° upon the fluid metal. Taking, then, the capacity of water for heat to be unity, that of mercury will be found from the above results to be 0·033. The capacity of any other body for heat may be determined with tolerable accuracy in the same way; the sides of the vessel, however, are liable to radiate more or less caloric, and will, of course, cause a slight deviation from absolute accuracy in the results.

Many plans have been proposed for estimating the capacity of bodies for heat. The method just described was followed by WILKE, CRAWFORD, KIRWAN, DALTON, and others; whilst DELAROCHE, BERARD, NEUMANN, and REGNAULT proceeded on the principle of allowing equal weights of bodies to be exposed to the same cooling medium, and observing the difference in the time which they required to fall to the same degree; or, inversely, the time was noted which the bodies, when subjected to the same temperature, required to arrive at the marked degree. The difference, of course, depended upon the capacity for caloric, and from this datum the latter was relatively estimated. LAVOISIER and LAPLACE endeavored to arrive at more correct data, by ascertaining how much ice the body dissolved in cooling down to the freezing point; but this method was likewise liable to error, for the ice retains a portion of water which has been liquefied, and, therefore, the measurement of the quantity dissolved cannot afford a perfectly correct estimate; besides, portions of what has been rendered fluid are liable to be frozen again, and in either case the results must be incorrect. DULONG and PETIT conducted their researches by allowing spheres of equal size, equally heated, to cool, and noting the time which they required to fall to a given point; this, of course, will depend on the relative amount of heat which they contain, provided the radiation is rendered equal. The capacity of bodies for caloric is expressed by *relative* and *specific* heat: the former is generally applied when the determination is made as regards the volume, and the latter when it has reference to the weight of the substances.

The following table shows the specific heat of the substances mentioned, between 32° and 212° Fahr. :—

Name.	Specific heat; water = 1.	Authority.
Arsenic,	0·0814	Regnault.
Antimony,	0·0508	"
Animal charcoal,	0·2608	"
Charcoal strongly ignited, ..	0·2415	"
" moderately heated, ..	0·2964	{ De la Rive and Marcet.

The specific heat of bodies varies with their state of expansion, or, in other words, with any alteration in the distance of their particles from each other. Mechanical compression, sufficient to produce a permanent alteration in density, is attended by a corresponding decrease in specific heat. REGNAULT found the capacity for heat of a piece of soft copper to be, in two experiments, from 0·09501 to 0·09455; but after subjecting it to an atomical disarrangement by hammering, the specific heat diminished, and became 0·0936 to 0·0933. When, however, the original state of the bar was restored by annealing, an increase was experienced, and two trials gave respectively 0·09493 and 0·09479. As with solids, so also is it with liquid and aeriform bodies. When these are compressed much heat is liberated; indeed, with aeriform bodies, the heat disengaged is so abundant as to be capable of igniting tinder and other inflammable materials.

The reverse takes place when gaseous bodies are allowed to expand, by withdrawing the pressure; and in proportion as the rarefaction is greater, so also is the capacity for heat of the expansive fluid augmented.

A beautiful example of this law exists in the atmosphere. It is well known from the observations of aeronauts, and those who have ascended high mountains, that the temperature of the air decreases in proportion as the region is elevated, and that this diminution borders closely upon 1° Fahr. for every three hundred feet. Even in tropical climes some of the mountains are perpetually capped with snow, at a definite altitude, subject only to some little variation arising from the nature and distribution of the land beneath. The cause of this cold is the attenuation of the air as it extends from the earth into space, by which its capacity for heat is so greatly increased that a far more elevated temperature would be required to maintain it at the same warmth as the atmosphere near the surface of the ground. The appended table, from DANIELL, gives the approximate distribution of heat by the dilatation of the atmosphere at the equator and poles, supposing the normal temperature at both these places to be respectively 80° at the former and 0° Fahr. at the latter :—

C

Altitude in feet.	Temperature at the Equator.	Temperature at the Poles.
0	80	0°
5000	64.4	— 18.5
1-0000	48.4	— 37.8
1-5000	31.4	— 58.8
2-0000	12.8	— 82.1
2-5000	— 7.6	— 109.1
3-0000	— 30.7	— 140.3

Taking the limit of the atmosphere to be forty-five miles high, it is probable that the most subtle and permanent gases would not only be condensed but even solidified by the degree of cold which would there act upon them, could the ordinary pressure on the surface of the globe be sustained.

Elevation of temperature also increases the capacity of bodies for caloric, and hence it requires the application of a greater heat to raise their temperature when they have combined with a large amount of caloric than in the contrary case. The appended table shows the increasing capacity of the bodies enumerated within the limits assigned:—

Name.	Capacity for heat between 32° and 212°.	Ditto between 32° and 572°.
Mercury,.....	0.0330	0.0350
Platinum,.....	0.0335	0.0355
Antimony,.....	0.0507	0.0549
Silver,.....	0.0557	0.0611
Zinc,.....	0.0927	0.1015
Copper,.....	0.0949	0.1013
Iron,.....	0.1098	0.1218
Glass,.....	0.1770	0.1900

Water ranks first of all bodies yet known in its increasing capacity for heat, at an elevated temperature. Between 22° and 32° Fahr. the specific heat of solidified water is 0.505, assuming it to be unity in the liquid state, and if converted into steam the specific heat of the vapor increases with its state of dilatation. This property contributes in no small degree towards moderating the rapidity of the transitions from heat to cold, and *vice versa*, in the atmosphere, owing to the large quantity of heat which is absorbed by or emitted from the water of the ocean, when the temperature exceeds or falls short of the normal range.

In the determination of the specific heat of vapors, much remains to be done, to arrive at satisfactory results.

DULONG and PETIT endeavored to establish the relation of the specific heat of bodies and their atomic equivalent. This relation they expressed by a general law, that the specific heats of elementary bodies vary inversely with their atomic weights; and that an atom of any one simple substance, whether small or large, has the same capacity for caloric, and requires the same quantity of this imponderable to raise its temperature through a given number of degrees, as an atom of any other element. REGNAULT, by observing that the product of the specific heat into the atomic weight is nearly a constant quantity, represented by 3.2°, advanced a considerable step towards establishing the existence of this general law; still, there are many exceptions which have not yet been reconciled with it.

LATENT CALORIC, OR HEAT OF FLUIDITY.—BLACK asserted, many years ago, that fluidity was owing to the chemical combination of matter with a certain amount of heat, which could not be detected by the thermometer. To this he applied the term *heat of fluidity*, or *latent heat*, assuming that heat, by its chemical combination

with matter, counteracted the cohesive attraction of the atoms of solids, and thus explaining the phenomenon of liquefaction, as that condition in which the cohesive and repellent forces are in exact equilibrium. This view of the subject appears to be well founded; and it is believed that the condition in which matter is found, as solid, liquid, or aeriform, entirely depends on the amount of caloric in combination with it. This has been proved with reference to most substances, and there is strong ground to believe that even the most refractory may be converted into an elastic vapor, and the most permanent of the latter class rendered solid, by the communication of heat on the one hand, and its abstraction on the other.

Solids very much vary in the phenomena which attend their conversion to fluidity; while many of them are transmuted at once to this state, others pass through various stages of softness previous to their assuming it. The following table expresses the melting or solidifying point of a few bodies:—

	Deg. Fahr.
Lead melts at.....	612
Bismuth,.....	476
Tin,.....	442
Sulphur,.....	232
Wax,.....	142
Spermaceti,.....	112
Phosphorus,.....	108
Tallow,.....	92
Oil of Anise,.....	50
Olive oil,.....	36
Ice,.....	32
Milk,.....	30
Wines,.....	20
Oil of turpentine,.....	14
Mercury,.....	—39
Liquid ammonia,.....	—46
Ether,.....	—46

It must be remarked, however, with regard to the above table, that when the preceding substances in a melted state are cooled down, they do not solidify as soon as the foregoing temperatures have been attained. A further quantity of caloric must be abstracted before they assume the solid form; and, under some circumstances, this abstraction of caloric may actually be indicated by a depression of the sensible temperature extending to several degrees before any change occurs. Thus, water, which, in the form of ice, always melts exactly at 32°, may be cooled down to 8°, or even to 5°, without altering its state of aggregation. To produce this curious effect, it is necessary that no solid substance be introduced into the water, and that it be kept perfectly still; for, should the least movement of the liquid be occasioned, it would immediately begin to solidify, and the mass would rise to 32°. The sudden rise of temperature is occasioned by the evolution of the caloric which was required to liquefy the mass, and, consequently, had remained insensible to the instruments usually employed for its detection. This caloric is generally called *latent heat*; but the same term is applied to that which is contained in solid bodies, as well as to the heat of fluidity.

Much caloric is always absorbed and becomes latent by the solution of solid bodies in various menstrua, and the degree of cold which this occasions is often very great. For philosophical, and often for industrial purposes, the method followed to effect a reduction of the

temperature is, to dissolve various mixtures of salts in water or spirit, and the amount of heat which is required for their solution or their reduction to the fluid state, being abstracted from these liquids, and rendered

latent, is sufficient to reduce the temperature of the whole mass to a greater or less extent. The following table expresses the proportions of various substances best adapted for producing cold:—

FRIGORIFIC MIXTURES WITH SNOW.

Mixtures.	Parts by weight.	Therm. sinks—deg.	Degrees of cold.
Chloride of sodium,.....	1	From any temperature	to — 5
Snow,.....	2		
Chloride of sodium,.....	2		
Chloride of ammonium,.....	1		
Snow,.....	5	to — 12	—
Chloride of sodium,.....	10		
Chloride of ammonium,.....	5		
Nitrate of potassa,.....	5	to — 18	—
Snow,.....	24		
Chloride of sodium,.....	5	to — 25	—
Nitrate of ammonia,.....	5		
Snow,.....	12		
Strong sulphuric acid,.....	1	from + 32 to — 23	55
Water,.....	1		
Snow,.....	3		
Concentrated hydrochloric acid,.....	5	from + 32 to — 27	59
Snow,.....	8		
Concentrated nitric acid,.....	4	from + 32 to — 30	62
Snow,.....	7		
Chloride of calcium,.....	5	from + 32 to — 40	72
Snow,.....	4		
Crystallized chloride of calcium,.....	3	from + 32 to — 50	82
Snow,.....	2		
Fused potassa,.....	4	from + 32 to — 51	83
Snow,.....	3		

In making the foregoing mixtures, if snow be not at hand, pounded ice may be employed with equal effect.

When mixtures of salts and water are taken, the

reduction is not so great; yet, when the compounds are finely powdered, and the solution rapidly effected, the cold produced is very intense:—

Mixtures.	Parts by weight.	Temp. falls—deg.	Degrees of cold.
Chloride of ammonium,.....	5	from + 50 to + 10	40
Nitrate of potassa,.....	5		
Water,.....	16		
Chloride of ammonium,.....	5	from + 50 to + 4	46
Nitrate of potassa,.....	5		
Sulphate of soda,.....	8		
Water,.....	16		
Nitrate of ammonia,.....	1	from + 50 to + 4	46
Water,.....	1		
Nitrate of ammonia,.....	1	from + 50 to — 7	57
Carbonate of soda,.....	1		
Water,.....	1		
Sulphate of soda,.....	3	from + 50 to — 3	53
Dilute nitric acid,.....	2		
Sulphate of soda,.....	6	from + 50 to — 10	60
Chloride of ammonium,.....	4		
Nitrate of potassa,.....	2		
Dilute nitrous acid,.....	4	from + 50 to — 14	64
Sulphate of soda,.....	6		
Nitrate of ammonia,.....	5		
Dilute nitric acid,.....	4	from + 50 to — 12	62
Phosphate of soda,.....	9		
Dilute nitric acid,.....	4	from + 50 to — 21	71
Phosphate of soda,.....	9		
Nitrate of ammonia,.....	6		
Dilute nitric acid,.....	4	from + 50 to 0	50
Sulphate of soda,.....	8		
Hydrochloric acid,.....	5	from + 50 to + 3	47
Sulphate of soda,.....	5		
Dilute sulphuric acid,.....	4		

The acids should be prepared by adding two parts by weight of the fuming nitric acid to one of water, and allowing the mixture to cool. When working with sulphuric acid, equal weights of strong acid and water are taken, and used after cooling.

A still more intense degree of cold may be attained by the rapid evaporation of liquids, such as bisulphide of carbon, ether, protoxide of nitrogen, and solid carbonic acid gas. By employing a bath of carbonic acid and ether *in vacuo*, FARADAY reduced the temperature

166° Fahr. below zero; and NATTERER, by means of bisulphide of carbon and protoxide of nitrogen, brought the thermometer to — 220°. The cause which operates in the case of the solution of solids in snow and water, or acids, is the same that induces the frigorific effect by rapid evaporation; but as the caloric which is rendered insensible or latent in the conversion of a liquid body to a gaseous state, is much greater than is necessary to convert a solid to the liquid form, hence it results that the depression of temperature produced by a rapid evaporation can be carried further.

Latent heat, the amount of which differs in different bodies, serves very important offices in the economy of nature, as well as in the chemical manufactures. When the temperature of the atmosphere in winter rises to 32°, masses of ice and vast accumulations of snow would suddenly liquefy, producing destructive inundations, were it not that in melting they must further absorb the heat of fluidity, which becomes latent, and thus the change is retarded and rendered gradual. In the manufactures, the importance of latent heat is illustrated by the employment of steam as the heating agent in numerous processes of distillation, evaporation, and carbonization; but the manner in which it acts in these cases will be better understood after some further explanation of the effect of heat upon liquids.

It has been shown that the change from the solid to the liquid form is the result of the combination of a certain amount of caloric with the substance, and that the heat so united becomes insensible to the thermometer, however delicate its construction. Instances of the absorption and disappearance of heat have been given in the melting of ice, metals, and other substances, capable of passing into the liquid state. In the fusion of metals, the temperature of the bath does not increase a fraction of a degree above the melting point, till the whole has undergone liquefaction, notwithstanding that heat has been pouring into the mass without intermission. The reason of this is, that as long as any of the metal remains solid, it abstracts all the excess with which the liquid may be charged, and combines with it to form more fluid. After the latter stage has been attained, if the temperature be still increased, the bath will continue to indicate a rising temperature till it acquires that degree at which the repulsive force of the caloric will have so far overcome the cohesion of the particles, as to expand them to such an extent that their gravity will be less than that of the air, bulk for bulk. The liquid will then be gradually transformed into vapor, and will manifest the phenomenon of ebullition, which is simply the commotion produced by the evolution of bubbles of the substance itself converted to the gaseous state, and which are generated by its union with the caloric supplied to the liquid. Whatever additional heat be now applied, the boiling fluid will continue to indicate the same temperature as long as any of it remains; and during the process, the vapor which escapes possesses *apparently* only the same amount of caloric as the liquid from which it is produced, but *actually* a greater amount in the shape of the additional *latent heat* by which it is converted into vapor.

These changes are more familiarly known as hap-

pening with water than with metals, for although the latter are frequently fused, they are seldom converted into vapor. During the melting of ice by the application of heat, the ice, or mixture of ice, and water, remains at 32° till the whole is melted; it is evident, however, that the water at 32° must now contain more heat than when, in the state of ice it indicated the same temperature. If heat continue to be applied, the water gradually acquires a temperature of 212°, at which point, provided the atmosphere is at the usual standard barometric pressure, and the liquid be contained in an open iron or copper vessel, it remains stationary. It is now rapidly converted into vapor, but both the liquid and vapor are still at the temperature of 212° Fahr. A little consideration will show that the heat which continues to flow into the liquid, is expended in converting it into steam; for as no indication of an increase is manifest, it must be evident that the surplus is rendered insensible in the process of converting the water into vapor. The quantity of heat necessary to effect this is much larger than is required to reduce the body from the solid to the liquid state. To estimate the amount of caloric expended and rendered insensible or latent in both cases, let a pound of water at 212° be mixed with the same weight of water at 32°, and it will be found that the mixture will indicate a medium between these points—that is to say, the pound of water at 212° will lose 90°, and the pound of water at 32° will gain 90°; so that the mixture will indicate 122°. But now let a pound of water at 212° be mixed with a pound of snow or ice at 32°, and the mixture will indicate only 51° Fahr., showing that the water has lost 161°, while the snow or ice has gained *apparently* only 19°. It is evident that the difference between these figures, or 142°, must have been absorbed or become latent in converting the snow or ice into water.

Applying the same test to steam or vapor of water at 212°, it will be found that one pound of water, which has been converted into steam, is sufficient to reduce six pounds and a quarter of snow or ice to the liquid state, and to raise it to 51°, from which it may be deduced that steam contains 967° of latent or insensible heat. LAVOISIER estimates the amount, in round numbers, at 1000°.

EBULLITION AND EVAPORATION.—During the ebullition of water in common metallic vessels at the ordinary pressure of the atmosphere, no amount of heat applied can elevate its temperature beyond 212°, provided the steam passes off freely; a fact which is well deserving of consideration in domestic economy. Many causes, however, tend to vary the boiling point of water and of liquids in general. If it be contained in smooth glass vessels, ebullition takes place at two or three degrees above the usual standard; hence, if a coil of wire be introduced into water contained in a smooth glass vessel, and near the point of ebullition, this process will commence immediately. All angular bodies, and more especially metals, introduced among the liquid, cause the boiling to take place even in glass vessels at 212°. The adhesion of the liquid to the sides of such vessels seems to be the cause of impeding the boiling, and sometimes of making

it to pass into vapor suddenly; hence in distilling in the laboratory the custom of introducing bits of platinum wire into the retort to facilitate the conversion of the liquid into vapor; without this precaution there is often danger of the retort being broken, or of the liquid operated upon being thrown over into the receiver. At each evolution of vapor that is formed during ebullition under these circumstances, the temperature falls to 212°; but when it has escaped, the contents of the vessel remain quiet till the temperature rises as before. Many substances, such as shell-lac, when applied to the interior of the vessel, prevent ebullition taking place at the usual degree; but the experiments of DORMY have proved that atmospheric air mixed with liquids influences their boiling point more than anything else, except pressure. He showed that the air which is dissolved in water acquires an increased elasticity, and forms minute bubbles in the interior of the fluid into which the steam dilates and rises to the surface. By long-continued boiling the air is nearly expelled; and in the course of some experiments it was found that the temperature could be raised to 360° in an open vessel without the phenomenon of ebullition taking place; finally, however, the disengagement of vapor was so sudden that it caused a loud explosive report, and shattered the vessel in fragments.

From what has been said, it is evident that the boiling point of liquids is not fixed, but is dependent upon various causes. The greatest effect is produced by the varying pressure of the atmosphere, which on an average is about fifteen pounds for every square inch of surface at the level of the sea; but the weight of the air varies at different heights, and according as it happens to be surcharged with watery vapor or not; consequently, at different elevations the boiling point will be different, and even at the same level the pressure or density varies so much as to cause a difference of four degrees or more of Fahrenheit's scale. It is absolutely necessary, therefore, to observe the pressure of the atmosphere when fixing the boiling point of liquids on the thermometer, and to make the necessary corrections. This is done by noting the height at which the mercury in the barometer stands at the time, and making the requisite allowance for any difference between that and the normal height of 29.92 inches, as shown by the following table, which embraces the extreme indications of the barometer at common levels, with the boiling points of water corresponding to these and the intermediate indications:—

Barometer indication. Inches.	Water boils. Deg. Fahr.
27.74	208
28.29	209
28.84	210
29.41	211
29.92	212
30.6	213

It thus appears, that under a diminished pressure water seethes at a lower temperature, and the same happens with other liquids. SAUSSURE found that, on the top of Mont Blanc, water boiled at 184° Fahr. In deep mines, on the contrary, it requires a much higher temperature than 212° to bring it to a state of ebullition. On this circumstance has been based the con-

struction of an instrument for determining the heights of mountains by the boiling point of water or other liquids.

When the pressure is removed by artificial means, as by creating a vacuum, the boiling point of water may be lowered about 145° under the usual temperature at which ebullition takes place. This has been turned to advantage in several manufacturing processes, where an exposure to the temperature of boiling water, under ordinary circumstances, for a length of time, would be prejudicial and sometimes destructive to the substances under treatment. The pharmacist and sugar-refiner are especially benefited by the application of this important fact in their respective processes. By operating under a low pressure, produced by creating a partial vacuum, the former can readily inspissate his vegetal juices to any desired extent without injury; whereas, if the same were attempted in an open vessel under the common atmospheric pressure, most of the active principle would be destroyed. In like manner, if the saccharine liquid of the sugar boiler were to be concentrated to the same degree to which it is usually carried in an open pan or boiler, nearly the whole of the crystallizable sugar would, by an allotropic molecular arrangement, pass to an uncrystallizable sirup. By an increased pressure the converse of this happens, and water may be made to attain a temperature of 300°, 400°, or upwards, before ebullition. An instrument known as PAPIN's digester, which is simply a strong metallic vessel with a safety valve, is constructed on this principle, and is used to macerate bones and other substances in liquids raised to a higher temperature than that of boiling water.

Solid bodies dissolved in water or other liquids produce, to a certain extent, the same effect as high pressure; generally, the elevation of the boiling point varies according to the nature of the substance in solution, but it uniformly increases with the same body till the liquid is saturated. Tables founded upon this law have been drawn up, for the purpose of estimating the amount of saline matter in a liquid from its boiling point.

Ebullition consists mainly in the conversion of the liquid into vapor, and so far is synonymous with evaporation; which differs from it, however, inasmuch as the latter takes place at all temperatures—whereas a certain range of heat is required, under every circumstance, before the former phenomenon is observed. This may be proved by allowing a shallow vessel containing water to remain exposed for some time; upon examination it will be found that a portion will have disappeared—or, in other words, it will have evaporated to the extent of the loss. Most fluids are susceptible of this change, but those which boil at a low temperature are more volatile than others: thus alcohol is evaporated much quicker than water, and for the same reason ether is converted into vapor much more readily than even alcohol.

Evaporation is affected by the temperature and hygrometric state of the air, and the extent of surface exposed. It is evident that the latter must influence the rate of conversion into vapor, because this alteration can only take place at the surface: hence the amount

of evaporation will be, *ceteris paribus*, in proportion to the superficies which the fluid presents. But when the air is surcharged with moisture, the change into vapor will be slow, even although the temperature be elevated, whereas, if it be dry, the fluid will disappear much quicker. In still air the evaporation is much slower than when a breeze or current of air is passing over the liquid; because, in the former case, the stratum of air immediately over the surface of the fluid becomes saturated and unable to take up any more moisture, whereas, when a current is established, a fresh and dry stratum is constantly presented to the liquid, and passes away loaded with vapour.

Evaporation, like ebullition, is greatly promoted by the removal of pressure; thus, by placing a cup containing ether or any other volatile fluid under the receiver of the air-pump and exhausting it, the fluid rapidly disappears, and an atmosphere of vapor is formed.

In all cases, however, where it is expedient that liquids should be quickly vaporized, heat is resorted to as the best and most ready agent. Heat, indeed, is the cause of evaporation at whatever degree or under whatever circumstances it takes place, just as it has been shown to be the cause of liquidity. Hence arises the important question, What is the least quantity of caloric required to effect the evaporation of a given quantity of liquid?—a question which bears on the economy of fuel in the generation of steam, and in many other manufacturing processes. Mr. SHARPE, of Manchester, arrived at the conclusion, that as the latent heat of vapor is increased with its degree of rarefaction, and as subtler vapor is obtained at low than at more elevated temperatures, there is no economy of caloric, and therefore no saving of fuel by evaporating or distilling liquids *in vacuo*. WATT further showed that the same weight of steam, whatever density it may possess, contains the same quantity of heat, its insensible or latent caloric being increased in proportion as its sensible is absorbed. Thus he found that a given weight of steam at 212°, and consequently possessing 180° of sensible heat above the freezing point, gave off 950° more when condensed by injecting upon it water at 32°, making, with the sensible heat, a total of 1130° above the point of freezing. Again, the same weight of steam at 250°, and therefore possessing 218° of sensible heat, gave out, on being liquefied at the same temperature, only 912° Fahr., which, with the sensible heat, amounted exactly to 1130° also. This he assumed, therefore, as the amount of caloric necessary to convert water at 32° into steam, either of a high or low tension; and hence, on this assumption, to ascertain the amount of latent or insensible heat in steam, at any temperature, all that is necessary is to deduct the sensible heat from 1130°, and the difference is the latent caloric.

These experiments appear to lead to the inference that, in the evaporation of liquids, generation of steam, distillation, *et cetera*, no material economy is gained by conducting these processes at low rather than at high temperatures; but the later and more carefully conducted researches of REGNAULT have shown that this assumption is not strictly correct, and al-

though the difference does not lead to serious errors in practice, yet in reality the sum of the latent and sensible heat increases for each degree of Fahrenheit, by a constant quantity equal to 0·305°. This is illustrated in the annexed table, in which it is assumed that steam possesses no sensible heat below Fahrenheit's zero :—

LATENT AND SENSIBLE HEAT OF STEAM AT DIFFERENT TEMPERATURES :—

Pressure in atmospheres.	Temperature.	Latent heat.	Sum of latent and sensible heat.
0·044	0°	1114°	1114°
0·180	32	1091·7	1123·7
1·000	212	966·6	1178·6
8·000	339	877·3	1216·8

The increase here shown offers, however, but a small inducement to perform the processes already alluded to at low temperatures—so far as saving of fuel is concerned; while the increased amount of sensible heat which may be utilized advantageously when the steam is generated under pressure, renders it expedient that the latter mode of generating it should be resorted to. This is the case especially when steam is employed as a source of heat in the carbonization of ligneous matters, in the distillation of liquids, and, occasionally, in the concentration of saline and extractive solutions. The large amount of caloric which steam possesses renders it peculiarly adapted to such purposes; and hence, in all those manufactures where the products are of a salifiable or an extractive nature, steam is now generally employed to concentrate the liquors. In the culinary art, also, it is found to be much more eligible as a source of heat than the common method of exposing the apparatus directly to the action of fire. It is especially adapted for drying manufactured goods and for purposes of ventilation; in the one case, it is conveyed through cylinders over which the goods are conducted, and in the other through iron pipes, so disposed that the heat shall be given off in the most effectual way. In the latter case, experience has shown that the boiler should have one cubic foot capacity for every two thousand cubic feet of air to be heated to a temperature of 70° or 80° Fahr., and that the conducting pipe must present a superficies of one square foot for every two hundred cubic feet of space to be heated.

Elastic Force of Steam.—When different liquids are heated to their boiling points, they produce very unequal quantities of vapor. Water yields it in larger volume than any other known liquid. The following table shows the volume of vapor produced by a cubic inch of each of the liquids enumerated at their respective boiling points :—

Cubic inch.		Cubic inches.
1 of water	expands to	1696 at the boiling point.
1 of alcohol	"	528 " " "
1 of ether	"	298 " " "
1 of turpentine	"	193 " " "

The great value of machinery at the present day in developing the resources of nations, and in fostering and extending commerce and internal intercourse, turns upon the expansive property of water under the

influence of heat. This, as already stated, is such as to make it the most efficient motive power; and although it requires a higher temperature, and consequently a greater consumption of fuel, to generate vapor from it than many other liquids, yet its superior elasticity in the shape of steam is such as to render it preferable to any of them, even supposing they could be had as cheaply. When the vapor of water is heated alone, the rate of expansion is the same as that of air or any other elastic gaseous mixture when subjected to an equal temperature, and it may be confined in red-hot vessels without a great amount of elastic force being acquired. It is otherwise, however, if some water be contained in the vessel or cylinder, for then the generation of fresh vapor causes an addition of elastic force to that already exerted, so that in time the pressure on the walls of the vessel becomes irresistible.

PAPIN's digester, already mentioned, or an apparatus constructed on similar principles, is resorted to for determining the elastic force of steam when subjected to a continued increase of temperature. This apparatus, which is represented in Fig. 15, is a globular vessel, A, furnished with a thermometer, *b*, a stopcock, *c*, and a long glass tube, *d*, affixed to a graduated scale, *e*; the tube is open at both ends—the lower one dipping into some mercury in the bottom of the vessel, and on which the water floats. A lamp, placed under the globe, causes the water to boil, and so long as the tap is left open, this happens at 212°; but if the steam which is produced be retained by closing the tap, the temperature no longer remains stationary at 212°, but rises progressively as the steam is accumulated; and the mercury, which before marked only a height equivalent to thirty inches in the tube, now ascends till it reaches twice or thrice that elevation, according as the elastic force of the steam is increased.

DULONG and ARAGO have made some researches upon this subject, which are valuable, inasmuch as they throw considerable light upon the mechanical effect of steam. The results are, therefore, appended in the following table, from which it may be seen, that as the temperature rises, a given increment of heat produces a greater effect in augmenting the elastic force than at a lower temperature. If the atmospheric pressure, or the elasticity of steam at 212° Fahr., be taken as unity, the elastic force of steam at 240° Fahr. will be about one and a half, and at 250° Fahr. will be equal to two atmospheres. Thus an increase in the quantity of heat indicated by 38° Fahr. doubles the elastic force, and it also appears from the table that a further increase of 25° trebles the elastic force, and a further increase of only 18° quadruples it. Thus the elastic

force evidently increases much more rapidly than the temperature. This circumstance has led to the introduction of high-pressure boilers as affording an increased motive power, with a less consumption of fuel, than when low-pressure boilers are used. The former have been found so advantageous, that, in mining and manufacturing districts, as well as for locomotives and steam vessels, high-pressure steam is now in general use:—

ELASTICITY OF STEAM AT HIGH TEMPERATURES.

Elasticity of steam, taking atmospheric pressure as 1.	Temperature Fahr.	Elasticity of steam, taking atmospheric air as 1.	Temperature Fahr.

COMBUSTION.—Allusion has already been made in the preceding pages to various sources of heat; but those which will fall to be considered in connection with the subject of this article, are certain material substances which, in the act of undergoing chemical changes, yield both heat and light. This process is termed combustion. At one period, and among the disciples of LAVOISIER in particular, oxidation and combustion were considered synonymous. It is true, that in most cases of combustion, as in that of a common fire, the effect is produced by the oxidation of the materials; but cases of combustion occur when no oxygen is present. Antimony, for example, burns when heated in an atmosphere of chlorine; copper, or iron, when heated with sulphur; potassium, with cyanogen, *et cetera*. These instances demonstrate the fact that oxygen is not essential to combustion, although it is eminently capable of supporting it; and being so extensively disseminated in the atmosphere, it acts as the almost universal agent in this phenomenon.

Though the term *combustion* is generally limited to cases of chemical combination accompanied with heat and light, yet it is sometimes extended to express the union of bodies with oxygen effected at a low temperature. Iron, for example, when exposed to moist air, undergoes a change in oxidizing, whereby its metallic characteristics disappear; the constituents of the blood are modified by a similar chemical process, but in neither case is light produced; and if heat is generated in the former, it is quite inappreciable even by delicate instruments. In both cases, however, the effect produced is sometimes characterized as a process of *slow combustion*.

In cases of vivid, as distinguished from slow combustion, the heat and light seem to be evolved from the

solid, liquid, or gaseous bodies which burn, and hence they are termed *combustibles*, while the gaseous atmosphere in which they are involved, such as oxygen or chlorine, is termed the *supporter of combustion*. It is evident, however, that this distinction is radically faulty, inasmuch as the phenomena of light and heat may be regarded as proceeding either from the one or the other. The combustible, usually so called, may be represented as supporting the combustion of the atmosphere in which it is enveloped, and the latter, regarded in this view, becomes the real combustible. In strictly philosophical language, the combustion proceeds from the combination, which can only take place at the point of contact; and therefore it is quite impossible to say to which of the bodies so combining is due the evolution of heat and light, or, in other words, which is the combustible and which the supporter of combustion.

Much difference of opinion exists as to the manner in which heat is produced, and the question is far from being solved at the present time. At one period it was thought that heat was a material constituent of the substance, which might be separated from it or combined with it like other substances. On this hypothesis all the gaseous bodies were regarded as compounds of the actual matter with the substance of heat and light, or *phlogiston*, as it was called; and when any one of these, such as oxygen, was made to unite with another body, and heat and light accompanied the combination, these phenomena were attributed to the evolution of *phlogiston*. Moreover, to account for the fact that some bodies, as metals, gained in weight by combustion, the *phlogiston* was supposed to be possessed of a principle of levity. LAVOISIER explained the evolution of caloric when certain bodies entered into combination, on the supposition that the specific heat of the substances before combustion was greater than that of the bodies produced, and that the difference was what was radiated or otherwise evolved from the burning body. Experiment, however, has shown that this theory is untenable, for in the case of the combustion of carbon, which is the commonest instance, the carbonic acid gas produced has a greater instead of a less specific heat than oxygen; and hence, in a case where caloric is actually given off, the result is found to be the very reverse of that which is implied in this explanation. More recently, THOMSON accounted for the effect on the assumption that every atom or molecule of simple bodies contains an equal amount of heat, and that, when a number of them combine, the caloric from one or more is expelled. But all these theories may be ranked as mere ingenious speculations. In the present state of knowledge, all that can be affirmed with certainty is the general principle, that heat is developed by chemical action.

Relative Value of different Combustibles.—The amount of caloric produced in the combustion of different bodies is variable, and the determination of the quantity so produced becomes a matter of the highest importance, as upon this depends the selection of particular substances for the production of heat economically. The course pursued in researches with this object in view is to burn a certain weight of

the combustible, admitting for this purpose only the smallest possible quantity of oxygen or air, and so to conduct the heat through water that it shall be entirely absorbed by it. From the quantity of liquid raised through a certain range of temperature, the value of the combustible under experiment is estimated.

Proceeding upon this plan, and comparing a number of results, WELTER concluded that the heat eliminated depended upon the quantity of oxygen taken up, and that the amount developed by equal weights of oxygen, when made to unite chemically with other bodies, how different soever they might be, was always the same. In this opinion he was supported by the researches of other chemists. DESPRETZ, by uniting one pound of oxygen with any of the following substances, found that the water raised from 32° to 212° Fahr. was, with

Hydrogen,.....	29.5 pounds.
Charcoal,.....	29 "
Alcohol,.....	28 "
Ether,.....	28.5 "

Although the law laid down by WELTER appears to be confirmed by these results, yet there are several facts with which it does not accord. When iron is oxidized and the generated caloric is collected in water, the quantity heated by it from 32° to 212° is fifty-three pounds, or nearly double the weight which the same volume of the gas consumed with the substances above enumerated raises to the boiling point. Zinc, tin, and many other metals, similarly treated, produce effects which differ in like manner from the results tabulated by DESPRETZ. Even the same quantity of oxygen produces unequal effects with the same body, when it is capable of combining with it in various proportions. Thus, when phosphorus is burned slowly, the amount of heat which it evolves in combining with one pound of oxygen is capable of heating only twenty-eight pounds of water to the boiling point; but when the combustion is conducted rapidly, so as to produce phosphoric instead of phosphorous acid, twice as much caloric is disengaged. Again, if charcoal be consumed with a limited supply of oxygen, so as to form carbonic oxide gas, and a quantity of this gas equivalent to one pound of carbon be ignited, it will be found that as much heat will be given off as will raise sixty-two pounds of water to the boiling point; whereas, if the carbon be ignited with its full complement of oxygen in the first instance, the heat obtained will be to the foregoing as 76.62, whilst the proportion of oxygen combined is as 2 to 1. From all these cases it appears that the quantity of heat developed by the combustion of a substance depends greatly upon the nature of the body itself. It cannot be denied, however, that the volume of oxygen which combines with the substance affords in most cases a pretty near approximation to the amount of heat developed in combustion; and hence the method in ordinary use for determining the heating power of combustibles by the reduction of litharge, which will be noticed further on.

But there are other considerations which must likewise be taken into account in estimating the relative value of different kinds of fuel. Very many substances which are capable of giving out considerable quantities of heat cannot be used for that purpose: first, because their

cost would exceed the limits of economy; and, secondly, because a too elevated temperature would be required to induce combustion. Such is the case with a great number of metals, which, under certain circumstances, are capable of evolving intense heat and light during their union with oxygen. On the other hand, there are many substances which may be made to undergo the process with comparative facility, but cannot be usefully turned to account, because they evolve obnoxious products, such as arsenical or sulphurous gases; others again require, for their combustion, a too complex apparatus, and too constant surveillance, to admit of their useful application.

The substances which combine the greatest facility of combustion with the production of a large amount of caloric, are carbon and hydrogen; and there is never wanting in the atmosphere a third, with which to combine—namely, oxygen. The product of the union of the first of these substances with oxygen, that is to say, of its combustion, is carbonic acid gas, a compound poisonous indeed when breathed alone, but destitute of odor, and colorless. Where common means of ventilation exist, there is no danger to be apprehended from this gas, and it cannot accumulate in the air to such an extent as to act injuriously; for on descending again to the earth it becomes the food of vegetals, by which it is analysed into its elements, and these are again rendered available for performing the same service. The combustion of hydrogen, or, in other words, its union with oxygen, yields only water, which, like the carbonic acid, is subjected to other transformations in nature's laboratory, whereby its elements are again separated, and therefore perform the same office over and over again without any diminution or loss of effect. It is impossible not to admire the wisdom and benevolence of that arrangement whereby these three elements are produced in quantities so enormous, they being far the most necessary materials towards the support of animal life. Regarded as sources of fuel, they are all conveniently stored in wood and other vegetals, of which a continual reproduction insures an abundant supply.

ARTICLES OF FUEL.—The substances usually employed as fuel are *wood*, *peat*, and *coal*, either in their natural state, or modified by peculiar treatment. The abundance of these in a country must always constitute a principal source of its wealth, more especially now that steam has become the moving power of manufacturing industry, as well as the great agent in locomotion. It is evident, therefore, that none of the productions of nature should be more carefully husbanded than those which constitute fuel. Every attempt also to improve the quality of inferior materials, so as to increase their efficiency as heat-producers, ought to be liberally encouraged; and some efforts in this direction have lately been made with much success.

Wood, peat, and coal, though so different in physical appearance, are nevertheless very closely allied in composition, all the three being chiefly composed of ligneous fibre, a compound of three simple elements—carbon, hydrogen, and oxygen. Physical effects have induced certain changes in some kinds of peat and

coal, which cause them to differ considerably in their properties from woody fibre; but, by observing the action which analogous artificial agencies exert upon the latter, a remarkable coincidence is observed, and sufficient data are found for inferring that woody fibre is the basis of these substances, although they have passed in the course of time through various chemical transformations. The extent of the changes thus induced may be, to some degree, inferred from the phenomenon of combustion. Woody fibre, when deprived of extraneous moisture, readily bursts into a flame upon being ignited, whilst many kinds of coal do not. The difference is caused, firstly, by the states of density of these substances; and, secondly, by the absence of hydrogen and oxygen in the coal. Porosity and the presence of hydrogen in combustible bodies facilitates rapid combustion. When hydrogen is a constituent, it is liberated at a temperature below redness, in union with a portion of the carbon, from all the pores of the substance, and forms around the latter an inflammable atmosphere, which bursts into flame at slightly increased heats; the evolution of this matter leaves the remainder open to the passage of oxygen, which effects its rapid combustion.

The production of flame is always connected in a remarkable manner with the presence of hydrogen, but in some cases the phenomenon may be observed where this element is absent; thus, when pure charcoal or anthracite coal is burned in a limited supply of oxygen or air, instead of carbonic acid being generated, an inflammable gaseous body results, which re-ignites when a further quantity of air or oxygen is admitted, and produces flame. A characteristic difference is, however, observed between the sheet of light which is given out by a combustible containing hydrogen, and that from carbonic oxide; the former is luminously brilliant, as is seen in gas, whilst the latter is dull, bluish, and attenuated. The property of producing flame determines particular uses for many species of fuel, such, for instance, as choosing cannell for the manufacture of gas, and of inflammable varieties for the heating of reverberatory furnaces where the materials are at a distance from the fire. A selection of this class, for purposes where local heat is wanted, such as in the reduction of ores and in the manufacture of iron, would be injudicious, and, consequently, the less inflammable, or such as have been divested of hydrogen, are in these cases resorted to.

WOOD—*Bois*, French; *Holz*, German.—This is the name given to the hard porous tissue of plants, through which sometimes the liquid sap is raised by capillary attraction, though more generally the latter traverses between the bark and these tissues. The wood of large trees is called timber, and is generally applied to architectural and domestic uses. It is only, however, in connection with its use as a combustible or source of heat that it will be discussed in the following pages.

Chemically considered, wood is composed of several substances, both of an organic and an inorganic nature, but of these the former alone are productive of heat. Woody fibre, or the tissue already noticed, constitutes the basis of the mass, whilst the sap, water, and other matters peculiar to the species of wood, make

up the remainder. All kinds contain water and woody fibre, so that the sap and extractive matters are the substances which determine the particular species of this organic production. Thus, many woods, especially the coniferous, are resinous; others, such as beech and birch, contain extractive matters; and many others, definite chemical compounds, such as tannin, and the like. All these may be removed by the successive action of water, alkalis, and alcohol; and although the principles in the several varieties are different, yet they all afford a close approximation in the quantity of carbon, hydrogen, and oxygen which the wood contains.

Various concurring circumstances tend to enhance the value of wood as a fuel, such as freedom from water, density, *et cetera*, and it is upon these qualifications that its marketable value turns.

Species.	Felling time.	Water.	Felling time.	Water.
Ash.....	End of January,.....	28.8.....	Beginning of April,.....	38.6
Sycamore.....	".....	33.6.....	".....	40.3
Horse Chestnut,.....	".....	40.2.....	".....	47.1
White Fir,.....	".....	52.7.....	".....	61.0

Sap is unequally disseminated in various parts of trees: in the trunk, it is accumulated more in the exterior than in the core, and still more in the branches than even in the outer portions of the trunk. Wood, cut at the proper time, retains from one-fifth to one-half its weight of moisture, part of which is lost by exposure to the air.

SCHUBLER and NEUFFER's experiments give the following as the per centage of water in the several species enumerated:—

	Water Centesimally.
Hornbeam— <i>Carpinus betulus</i> ,.....	18.6
Willow— <i>Salix caprea</i> ,.....	26.0
Sycamore— <i>Acer pseudo-platanus</i> ,.....	27.0
Mountain Ash— <i>Sorbus aucuparia</i> ,.....	28.3
Ash— <i>Fraxinus excelsior</i> ,.....	28.7
Birch— <i>Betula alba</i> ,.....	30.8
Wild Service Tree— <i>Crataegus tormin</i> ,.....	32.3
Oak— <i>Quercus robur</i> ,.....	34.7
Pedicle Oak— <i>Quercus pedunculata</i> ,.....	35.4
White Fir— <i>Pinus abies dur.</i> ,.....	37.1
Horse Chestnut— <i>Æsculus hippocast.</i> ,.....	38.2
Pine— <i>Pinus Sylvestris L.</i> ,.....	39.7
Red Beech— <i>Fagus sylvatica</i> ,.....	39.7
Alder— <i>Betula alnus</i> ,.....	41.6
Aspen— <i>Populus tremula</i> ,.....	43.7
Elm— <i>Ulmus campestris</i> ,.....	44.5
Red Fir— <i>Pinus picea dur.</i> ,.....	45.2
Lime Tree— <i>Tilia europæa</i> ,.....	47.1
Italian Poplar— <i>Populus italica</i> ,.....	48.2
Larch— <i>Pinus larix</i> ,.....	48.6
White Poplar— <i>Populus alba</i> ,.....	50.6
Black Poplar— <i>Populus nigra</i> ,.....	51.8

From the numerous experiments performed by CHEVANDIER, with the view of determining the loss sustained by woods of different ages, and by the several parts of the same tree when exposed to the air during stated periods, it may be inferred, that so far as the abandoning of moisture to air was observed, the soil and locality where the trees grew did not affect the results. The samples submitted to examination were exposed in a shed, which protected them from rain as well as from the sun's rays, and the moisture was determined at the several stages, by drying a portion of the sample in the form of sawdust, at a temperature of 284°

Amount of Moisture in Woods.—A remarkable variation is observed at stated seasons, in the quantity of soluble matter—sap—which is present in all kinds of woods: thus, in spring, when the tree is in active growth, the amount of water, *et cetera*, is much greater than at the close of autumn, or the middle of winter, when it is in a kind of normal state. The practical benefit of this knowledge is, that trees, whether intended for fuel or timber, are, or should be, felled in the latter seasons; although, when they are cultivated for the principle of the sap, such as tannin, quinin, *et cetera*, it is more advantageous to cut them when the flow is at its full.

SCHUBLER found in woods felled at the end of January and the beginning of April, an extensive difference in the amount of contained moisture, as may be seen from the appended results:—

Fahr. *in vacuo*, till it ceased to lose weight. By this procedure, it was found that the maximum loss by exposure was sustained, in the greater number of cases, after a period of a year and a half, although many specimens required two years to reduce their hygrometric contents in the same degree. It appeared, likewise, that the resinous varieties part with their water more freely than the non-resinous; they, on the other hand, absorb water with greater avidity when exposed to moist air than the latter. The softer non-resinous woods always contain more water when cut down than the harder kinds, but they part with it more freely, and can be desiccated to a greater extent than the latter.

The following is a synopsis of the results of researches on this subject, transcribed from the valuable treatise of RICHARDSON and RONALDS:—

1. MEAN QUANTITY OF HYGROMETRIC WATER CONTAINED IN RESINOUS WOODS.

Parts of the Tree.	Per Centage of Water.
Trunk-wood half a-year after felling,.....	29
Brush-wood ".....	32
Young Branch-wood ".....	38
Trunk-wood in the driest state,.....	15
Brush-wood ".....	15
Young Branch-wood ".....	15

2. MEAN QUANTITY OF HYGROMETRIC WATER CONTAINED IN THE NON-RESINOUS WOODS.

Parts of the Tree.	Per Centage of Water.
Trunk-wood half a-year after felling,.....	26
Brush-wood ".....	34
Young Branch-wood ".....	36
Trunk-wood in the driest state,.....	17
Brush-wood ".....	20
Young Branch-wood ".....	19

These results may be viewed as the minima, because the single specimens would be more thoroughly exposed than if made up into stacks; and it may, therefore, be inferred, that after exposure under favorable circumstances during a year, the wood still retains about one-third of its weight of moisture, for the expulsion of which a prolonged heat is required. In

ordinary air-dried firewood, this amount of water, together with that which results from the oxygen and hydrogen contained in it, is vaporized at the expense of the carbon, and the consequence is, that much of its value as fuel is lost when used in this state. In such applications where a brisk temperature is indispensable, the material is never used after merely air-drying, but is exposed to such a degree of heat as will drive off this moisture, so that, when ignited, the entire weight may be serviceable for the generation of heat. To do this thoroughly requires great care, because, unless the heat is sufficiently elevated, the moisture will not be removed, and when it is capable of exerting a thorough hydrotic effect, the constituents of the wood will be apt to arrange themselves so as to form gaseous matters, which are dispelled into the air, and thus a loss to some extent is sustained. Even when so treated that it does not retain any moisture, it becomes so hygrometric, that, upon exposure, it readily assimilates from eight to ten or more per cent. of water even in dry weather.

Density of different Woods.—When felled, nearly all kinds of wood are lighter than water, although the solid portions are possessed of a much higher density than this liquid; a few are, however, heavier than water, but these are the harder kinds, in which the cellulose is so closely packed together, that very little room is left for the retention of air. In their ordinary state, the woody matter, water, and air, concur to confer the gravity, but as the latter bodies considerably vary in amount, much difficulty is attendant upon the proper determination of the density. It will be understood, however, that so far as the moisture is concerned, it acts a neutral part, and the greater gravity of the solid portions is reduced by the volume of air in the pores. Again, as the hydrogen and oxygen of the woody fibre, as will be seen further on, are present in the ratio of their existence in water, or nearly so, and so solidified that they make up about the same volume as when actually combined in the form of water, it is evident that the greater weight of any specimen must be owing to the larger amount of carbon in the same bulk, excepting the slight difference which is due to the mineral constituents. The following table exhibits the density of several kinds of wood, according to BRISSON, water being taken as unity :—

Variety of Wood.	Density.	Variety of Wood.	Density.
Pomegranate,	1.35	Maple,	0.75
Ebony,	1.33	Cherry-tree,	0.75
Dutch Boxwood,	1.32	Orange-tree,	0.70
Heart of Oak—sixty		Elm—the trunk,	0.67
years old,	1.17	French Walnut,	0.67
Medlar,	0.94	Pear-tree,	0.66
Olive,	0.92	Spanish Cypress,	0.64
French Boxwood,	0.91	Lime-tree,	0.60
Spanish Mulberry,	0.89	Hazel,	0.60
Beech,	0.85	Willow,	0.58
Ash—the trunk,	0.84	Male Fir,	0.55
Spanish Yew,	0.80	Spanish White Poplar,	0.52
Apple-tree,	0.79	Female Fir,	0.49
Dutch Yew,	0.78	Poplar,	0.38
Plum-tree,	0.78	Cork,	0.24

When common woods that are thoroughly dried and rasped so as to destroy their porosity are weighed with proper precautions, their density is found to be higher

than that of water; and RUMFORD remarks that the solid portion of all the species of wood, wherever and under whatever circumstances grown, exhibits a remarkable identity in point of gravity, which he estimates at 1.46 to 1.53. It is to be observed, however, that the actual specific gravity of wood varies, in the same variety, with its age, the nature of the soil upon which it has been grown, and its site in relation to the prevailing wind; also, that young woods are specifically heavier than the older ones. The condition of the woods when the preceding densities were taken is not stated; the following table, based on different authorities, is therefore more satisfactory :—

Variety of Wood.	Hartig.		Wernk.	Winkler.	Mushenbroek.
	I. Recently Felled.	II. Dried in Air.			
Common Oak,	1.0754	0.7075	0.6441	0.663	0.929

Ground Willow, ..	0.7155	0.5289	..	0.501	..

The numbers given by each of the authorities in the preceding table can only be received as an approximation to the truth; but WINKLER's are probably the most trustworthy, because, in making his observations, the bulk of wood—one cubic inch—was the same in every instance, and the specimens were exposed in a heated chamber during six months, so that all contained an equal amount of water at the time of the experiment.

The principal difficulty experienced in attempting to determine the gravity of different kinds of wood, arises from the absorption of air into the pores and its subsequent expulsion. MARCUS BULL in his experiments removed this cause of error to a great extent, by coating the samples with a varnish having the same gravity as water. This insured the retention of the air in the pores, and admitted of arriving at a true approximation, although this appeared less than when quantities of the enclosed air were allowed to escape, as generally happens on immersing dried wood in water. Before citing his results, however, the appended table, containing KARMARSH's recent determinations, is placed before the reader, as affording a comparative view of the specific gravity of different kinds of wood in the green and in the dried state, with the mean weight of one cubic foot of the dried material :—

contains more carbonaceous matter in the same bulk. The condition of equal dryness, however, should not be overlooked, as without taking this into consideration the gravity deduced would be erroneous. From two-fifths to one-half the bulk of a stack of wood is interstitial space, even when the logs are of fair proportions; this is, however, much increased when small or crooked billets enter into its composition. Hence, in a stack, the per centage of solid matter compared with the bulk of the whole is very much less than that given in BULL's table. At the same time, it is only the quantity of woody matter that renders the material valuable as fuel; and a much nearer approximation to this can be arrived at when it is purchased by weight, than if the content is estimated by measurement. When, however, the purchaser is compelled to adopt the latter course, he should remember that the largest and straightest, as also the driest and densest varieties, are the surest to afford him an adequate value; the light, soft, and green woods not possessing sufficient matter to endue them with heating power in proportion to their bulk.

VALUE OF DIFFERENT KINDS OF WOOD AS FUEL.

—Very many considerations are to be taken into account in selecting wood as fuel—namely, the quantity of heat to be generated, the distance to which its effects are required to extend, and the length of time that the temperature must be sustained.

When soft light woods are burned, their action is brisk but transitory, their porosity favoring the rapid evolution of the volatile inflammable gases to which a part of their substance is converted by the heat; moreover, this looseness of texture allows the transmission of air freely through the mass of charcoal left, and, consequently, effects its rapid combustion. A remarkable exception indeed is cork-wood, which, although very light, affords more charcoal proportionally than any other species. When the wood is hard and compact, the heat cannot traverse it so freely; and the result is, that the interior portions undergo a kind of consecutive distillation, the volatile matters being slowly disengaged from the surface. When these have produced their effect, a charcoal remains of a dense and close character, weighing fifteen or twenty times more than that which light wood produces. Submitted to combustion, the charcoal from dense wood burns much more slowly, owing to the smaller surface which it presents to the air, than that from the softer kinds. These facts lead to the conclusion, that the principal effect of soft light woods is produced by the flame, the charcoal they afford being comparatively of little value. The contrary is the case with heavy woods, the flame from which is feeble compared with the others; but their charcoal is far superior, and more than counterbalances the difference.

It has been shown, in a preceding part of this article, that incandescent charcoal is very much superior to flame in radiating power; or, in other words, the quantity of caloric given off from charcoal is considerably greater than that emitted from flame; and as the denser woods produce, for equal weights, a much larger amount of charcoal than the lighter kinds, it follows that much more heat will result from the former.

Nevertheless, although light woods are less adapted for all heating operations in which radiation plays an important part, yet they may be employed with advantage where it is required to communicate an elevated temperature to objects distant from the fire-place, or a uniform temperature to solid bodies in large masses. Such are the reasons of their being preferred for glass-works, porcelain manufactories, *et cetera*; and even if a naturally dense material be employed for these purposes, it is brought to a suitable state by splitting it up into thin pieces, so as to render the combustion quicker, or to avoid the introduction of a useless mass of air into the furnace. On the contrary, blocks of dense wood are preferable for the heating of boilers, and other similar purposes, because, in this case, the radiant matter is required to act directly on the surface to be heated, which communicates by contact the heat to the liquid in the interior, through which it is then diffused by convection. The superiority of the denser over the softer woods for consumption in ordinary household fires, where radiation performs the most important part, is a fact universally recognised in practice. For stoves, also, and for heating apparatus in general, the former are found to be more advantageous, because they afford a much more regular and prolonged heat than the lighter woods, without involving the necessity of constantly adding fresh material to maintain the fire. On the other hand, apart from these considerations, the actual calorific effect of the same weight of dense and light wood is nearly equal. This has been proved experimentally by MARCUS BULL. Operating with a stove so constructed as to lose the least possible amount of heat, he found that the widest proportions between numerous specimens were as fifteen to sixteen.

In England, where wood is scarce and coal fields are numerous and extensive, the former is little employed as a fuel, except for some special purposes: but this is not the case in all other nations, and some European states in particular are almost entirely dependent upon wood for common consumption. On the Continent, firewood is divided into three kinds, namely, *new wood*, *float wood*, and *peeled wood*. The first is that which has been conveyed by boat or waggon from the forest to the place of its consumption; the second, that which has been floated upon the waters in the form of rafts, a mode of conveyance which causes a considerable quantity to be submerged during the passage; lastly, the peeled wood is limited to oak and certain other species, the barks of which have been removed for the sake of the principle they contain: it is generally composed of the smaller branches, and used in dwellings. Much of the value of the floated wood is lost by its submergence in the water, and this, to a great extent, counteracts the advantages of cheap transport. The loss arises from the solution of the principle of the sap in the water, and is visible in the density as well as in the volume, sometimes amounting to one pound per cubic foot.

SOLID CONSTITUENTS OF WOOD.—Fibrous matter, water, sap, and mineral salts, are the proximate principles of wood of every description. The amount of water contained in different woods has already received a share of attention, and as the sap is of a different

nature in every species, to enlarge upon it in all its varieties would unduly prolong this article. The further explanation of the proximate principles of wood will, therefore, be confined to the cellulose, lignin, or woody fibre, and the mineral constituents.

Lignin.—Woody Fibre or Lignin constitutes, as already stated, the main bulk of trees, and mostly all plants, varying in texture from the delicate and friable pith to the hard shells of the seeds, and the more dense and indurated vegetal ivory or perisperm of the seeds of the phytelphas. Regarded in conjunction with the mineral matters, it may be termed the skeleton of their structure, wherein is contained the various secretions and other principles. When the fine raspings of wood are treated successively with boiling alcohol, water, weak solutions of potassa, dilute hydrochloric acid, and ultimately boiled repeatedly with distilled water, there remains a white substance, which, when dried at 212° , is this *cellulose* or *lignin*. Not only may it be procured from the hard wood; but the pith of trees and plants yields it even more freely. If this pith be reduced by rasping, and then washed successively with hot and cold water, digesting in a weak solution of potassa, and afterwards subjecting it to the action of chlorine gas, the fibrin will be readily obtained. To complete the process, however, the digestion with the alkali is repeated, and this is succeeded by another with acetic acid, when, after affusing well with distilled water, and drying, a very pure lignin results. Many substances—such, for instance, as linen, cotton, paper, *et cetera*—afford lignin in a much purer state than wood, owing to the treatment which the fibre of flax and cotton undergoes to prepare it for those manufactures.

Pure lignin is tasteless, colorless, and insoluble in water, alcohol, ether, and essential oils; it has a specific gravity of 1.5, and is resolvable into other compounds by acids, such as nitric and sulphuric. The latter, in a concentrated state, converts it first into gum or dextrin, which may be afterwards resolved into grape-sugar. To effect this, one hundred parts of lignin—or clean bleached cotton or linen, answers the purpose—are treated with one hundred and forty of concentrated sulphuric acid in such a manner as to avoid the evolution of heat, or any charring; the mixture will readily admit of being triturated into a magma, which is soluble in water. By treating the aqueous solution of this mucilaginous matter with chalk, and straining or filtering, a liquid is obtained, from which alcohol separates a gummy precipitate; and this, after being elutriated with the spirit, and then dissolved in water acidulated with sulphuric acid, and boiled for some time, passes into grape-sugar.

It might be inferred from these results, that strong sulphuric acid converts lignin into amidin and dextrin; and, finally, into glucose or grape-sugar; yet the evidence in proof of the first change is not very distinct, although, on the application of the sulphuric acid to the substance, if a solution of iodine be added, a deep blue tint will appear. To show that the transformation to starch is effected, SCHLEIDEN directs that clean cotton wool be wetted with water, then squeezed dry, and afterwards spread upon a flat dish, and moistened with a mixture of three parts of sulphuric acid and

one of water; after about half a minute, an aqueous solution of iodine is added. With this treatment the blue iodide of starch does not fail to make its appearance.

Sulphuric acid reacts with great vigor upon wood and lignin, especially when heat is applied, giving rise to sulphurous, acetic, and formic acids, besides producing a black magma, from which water washes out those bodies, and leaves the carbonaceous residue to the extent of forty-three per cent. of the wood employed.

Nitric acid, in the concentrated state, decomposes lignin, changing it into the peculiar body xyloidin, which has nearly the same characteristics as that obtained from starch by similar treatment. The *gun-cotton* of SCHÖNBEIN, which is prepared by immersing cotton wool for a short time in equal parts of concentrated sulphuric and nitric acids, and washing under a stream of water and drying, is probably either a peroxide or a nitrate of lignin.

Hydrochloric acid, on being boiled with lignin, turns red, and ultimately brown. In the solid state, it becomes black, but does not dissolve in the acid. When this substance is washed and dried, it burns with flame, showing that it is only modified lignin, and not entirely carbonized. Fused potassa, or a strong solution of this alkali, changes a portion of the matter into oxalic and acetic acids, which combine with the base; the alkaline liquor, when treated with acids, parts with a modified lignin which is blued by iodine.

From what has been said of the behavior of lignin, more especially with sulphuric acid, it may be inferred that its composition is analogous to that of amylaceous compounds, or, in other words, that it is made up of the elements, carbon, hydrogen, and oxygen; the latter two being in that proportion in which they form water. GAY-LUSSAC and THENARD were the first to arrive at the conclusion that this proportion existed between these two elements, and the analyses of PROUT and others corroborated this view of the subject. To show the identity of lignin in the extensive circle of plants in which it is found, was a work undertaken and successfully accomplished by PROUT—not, however, by having recourse to numerous analyses of the principle prepared from different plants, but by taking two products of very opposite physical characteristics, and submitting them to ultimate analysis. These were portions of lignin from the *box* and *willow*; the former being one of the densest, and the latter one of the lightest species of woods. After preparing the lignin by repeated treatments with boiling water and alcohol, *et cetera*, it was submitted, after desiccation in air, to analysis, which gave the following numbers:—

	Centesimally.	
	Box.	Willow.
Carbon,	42.7	42.6
Water,	57.3	57.4
	100.0	100.0

By exposing the lignin thus analysed to a temperature of 212° , as long as loss was sustained, it was found that 14.6 per cent. of the weight of the box and 14.4 per cent. of the willow disappeared. Upon exa-

mination, the dried substance showed the annexed proportions:—

	Centesimaly.	
	Box.	Willow.
Carbon,	50	49.8
Water,	50	50.2
	100	100.0

By comparing these numbers with the figures given by GAY-LUSSAC and THENARD, as representing the composition of the lignin of beech and oak, namely:—

	Oak.	Beech.
Carbon,	52.53	51.45
Water,	47.47	48.55

or specifying the quantity of the water-producing elements thus:—

Carbon,	52.53	51.45
Hydrogen,	5.27	5.41
Oxygen,	42.20	43.14

the coincidence of composition will become apparent. LIEBIG assumes, from the analysis of GAY-LUSSAC and THENARD, that the formula is $C_{36}H_{22}O_{22}$; but calculating from the numbers obtained by PROUT, it is $C_{36}H_{24}O_{24}$.

By the action of heat, the hydrogen and oxygen in this body are made to unite, and, consequently, so far as the estimation of the value of lignin as a fuel is measured by the oxygen assimilated, they play no part, although it must be admitted that a certain quantity of caloric is disengaged by the chemical action which is produced by their union, notwithstanding that this may be rendered latent by the dispersion of the water so generated in the form of steam. It is, therefore, the carbon which operates in developing caloric by combining with oxygen, of which one hundred and thirty-eight parts are required to effect the conversion of one hundred parts of wood, represented by 52 of carbon, into carbonic acid. The caloric produced in this reaction is capable of melting 4,888 parts of ice, or of raising 3,666 parts of water from 32° to 212°. With these theoretical deductions, the practical results of RUMFORD and HASENFRATZ are in perfect accordance, giving 3,600 to 3,680, as the equivalent for dry woods. It must be observed, however, that all the heat is not produced by the carbon of lignin, as assumed in the above calculation; because the principle of the sap is retained. This, however, approaches so near in composition to woody fibre, and its quantity is so minute, that it does not cause any remarkable difference between the results of the ultimate analysis of dry wood and pure lignin, as the following table drawn up from the determinations of SCHÖDLER and PETERSON shows:—

Species of Wood.	Carbon.	Hydrogen.	Oxygen.
Pure woody fibre,	52.65	5.25	42.10
Quercus robur,	49.43	6.07	44.50
Fraxinus excelsior, ...	49.36	6.075	44.57
Acer campestre,	49.80	6.31	43.89
Fagus sylvatica,	48.53	6.30	45.17
Betula alba,	48.60	6.375	45.02
Ulmus campestris, ..	50.19	6.425	43.39
Populus nigra,	49.70	6.31	43.99
Tilia europæa,	49.41	6.86	43.73
Salix fragilis,	48.44	6.36	44.80
Pinus abies,	49.95	6.41	43.65
Pinus picea,	49.59	6.38	44.02
Pinus sylvestris,	49.94	6.25	43.31
Pinus larix,	50.11	6.31	43.58

It should be remembered, however, that the ash which, as will be presently seen, averages from one per cent. to a much higher proportion, has not here been taken into account, and, consequently, that the difference is greater than it would be, if the mineral ingredients were left out. CHEVANDIER has investigated some woods, taking cognizance of this fact, and the several specimens being dried at 284°, afforded the following results:—

ELEMENTARY COMPOSITION OF SOLID WOOD AFTER DEDUCTING THE ASH.

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.	Mean of Analyses
Beech,	49.89	6.07	43.11	0.93	7
Oak,	50.64	6.03	42.05	1.28	5
Birch,	50.61	6.23	42.04	1.12	4
Aspen, ...	50.31	6.32	42.39	0.98	3
Willow, ..	51.75	6.19	41.08	0.98	2

ELEMENTARY COMPOSITION OF BRUSHWOOD AND BRANCHES AFTER DEDUCTING THE ASH.

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.	Mean of Analyses
Beech, ..	50.08	6.23	41.61	1.08	8

Birch,	51.93	6.31	40.69	1.07	3
Aspen, ...	51.02	6.28	41.65	1.05	2
Willow, ..	54.03	6.56	37.93	1.48	2

On the whole, it appears from what has been stated, that carbon, oxygen, hydrogen, and nitrogen, are the essential ultimate elements of vegetal products, and that the proportion in which they combine is very nearly the same in different plants. It is, therefore, not a little remarkable, that the composition of even the same plants is found to vary slightly in different parts. This might be expected in regard to the distinct organs—such as the pith, the wood, the bark, and the leaves—but not in regard to different complete portions of the same organic structure. Even in the latter, however, a sensible variation exists in the root, the trunk, and larger or smaller branches. M. VIOLETTE examined various portions of the completely organized structure of the same tree, with the view of determining this point. The subject of his experiments was a healthy cherry-tree, thirty years old, which was carefully dug up in the month of October, taking care to preserve the roots and rootlets entire and without injury. Samples were taken from the trunk, the branches, and the roots, as represented in Fig. 16, at *a*, *b*, *c*, *d*, *e*, *f*, *g*—all cut of equal thickness and enclosed in paper capsules, which were deposited during five hours in the bottom of a receiver, in which a current of steam from the boiler was made to circulate. By this exposure to air and to the temperature of about 172°, they all acquired an equal desic-

Fig. 16.

cation, and, after this treatment, they were well dried by enclosing them in flasks. The results which were arrived at by submitting these woods to analyses are subjoined, and the operator states that they were not accepted till the repetition of the process corroborated them:—

COMPOSITION OF WOOD CUT FROM VARIOUS PARTS OF THE SAME TREE.

Nature of Wood.	Elementary substances found in 100 parts of wood.

Mineral Constituents.—When wood is burned, it always leaves a certain amount of residue or ash, which consists of various alkaline and earthy salts that have been taken up from the soil with the sap. The bases or metallic oxides of this ash are potassa, soda, lime, oxide of iron, and sometimes oxide of manganese; one or more of which are united with silicic, carbonic, sulphuric, and phosphoric acids, chlorine and sulphur. All woods have not the same per centage of inorganic matter contained in them, and, as may be seen in the preceding table, it varies remarkably in different parts of the same tree, and also with its age.

According to SAUSSURE, the quantity of ash yielded by—

1000 parts of barked young oak branches was....	4 parts.
1000 parts of their bark,	60 "
1000 parts of an oak trunk 56 feet diameter,	2 "
1000 parts of its bark,	60 "

BERTHIER, KARSTEN, CHEVANDIER, and others, have likewise directed their attention to this subject, employing air-dried wood as the subject of their experiments. The results are appended:—

ASH IN A HUNDRED PARTS.

ACTION OF HEAT ON WOOD.—Having explained the constituents of wood, it remains now to examine the effects of heat upon it. As the tendency of caloric is to subvert the power of the existing affinity

between the elements of complex bodies, as well as to change their physical appearance, the simpler the substances submitted to its action—that is, the fewer elements composing them—the greater is the force with which they are held in combination, and the better do they resist the influence of caloric. When several bodies enter into the composition of a substance, it readily yields to the decomposing effects of fire, especially if the constituents have an affinity for one another, whereby simpler combinations are produced. Products of organic growth are generally of this class, as they include several elementary matters which have a remarkable tendency to arrange themselves into simpler and more persistent compounds. Some of the ingredients of these bodies are of a volatile nature; hence, as soon as the force of the heat applied overbalances that of the affinity which binds them together in the peculiar state in which the vitality of the plant arranges them, they assimilate and disperse, whilst others are left in the solid state. When the matters submitted to the action of heat are out of contact with air or oxygen, the quantity and number of the compounds formed depend, for the most part, upon the intensity of the temperature applied; but when oxygen or air is admitted, and the action of the heat is still exerted, the bodies, already modified, will undergo another change, from which will result compounds of the simplest and most permanent character. The latter transformation is always accompanied by the phenomena of combustion, whilst the former is termed dry distillation.

The constituents of organic matters, acted upon by heat in the presence of air or oxygen, unite with the latter element, and form with it the simplest and most stable compounds which it is possible for them to enter into. This is shown in the conversion of the carbon, hydrogen, and oxygen of such bodies into carbonic acid, CO_2 , and water, HO —two of the simplest, and at the same time most permanent combinations. In the other method of acting with heat upon organic substances—that is to say, in close vessels or out of contact with air—the results are by no means so simple as those just described; because the conditions necessary for caloric to exert its full effect upon them are not supplied; and hence, although the compounds formed are not so complex, and are more permanent than those from which they have been generated, yet they are far from being the simplest and the most persistent.

From the moment when the decomposing agency of heat begins to overcome the existing affinity of the elements in the organic body, three circumstances concur, either to multiply the formation of distinct but definite compounds, or to yield particular ones in larger quantities: these are, as already intimated, the temperature; the natural affinity of the existing elements, more especially at the moment of their liberation in the nascent state; and, lastly, their volatility. The effects of the temperature are first directed to the expulsion of oxygen and hydrogen, two elements which, from their permanently gaseous nature, are disengaged; they have, however, a very powerful affinity for one another, and, consequently, at the instant of their liberation, this affinity is exerted, and

they pass off, in conjunction, as water. When the two gases are present in that proportion in which they constitute water, a very low temperature, comparatively, will be sufficient to bring about their separation from the burning body in the manner indicated; but, on the other hand, if they be contained in a different proportion, then will the excess of the one or the other, at the instant of its liberation, attack the more fixed element—carbon—and give rise either to permanent gases, such as light carbide of hydrogen and olefiant gas, or to oily products of an analogous constitution.

Products of the Combustion of Ligneous Matter.—The number and nature of the bodies which, by a proper management of temperature, might thus be produced are still open to research. Those which have been identified are water, ammonia, acetic acid, pyroxylic spirit, or wood naphtha, and a mixture of resins and ethereal oils, denominated tar. By submitting the tar, especially if derived from coal, to further distillation and various other chemical agencies, it is resolved into a variety of bodies; such as paraffin, picamar, creosote, kapnomor, pitacall, and naphthaline—compounds discovered by REICHENBACH—pyrogenous resin and numerous oils, besides coal-tar naphtha, which contains various basic and acid bodies. In addition to these, a number of gaseous compounds is produced, such as carbonic acid and carbonic oxide, light carbide of hydrogen, *et cetera*. The nature of the products will vary according as oxygen or hydrogen preponderates in a fuel; thus, when it is rich in oxygen, the greater will be the production of carbonic oxide and carbonic acid, and the formation of hydrogen compounds will be limited, whereas, if hydrogen be in excess, the latter will be most abundant. How large soever the proportion of both elements may be, it will be insufficient to eliminate the whole of the carbon in the substance; hence, when vegetal matters are subjected to destructive distillation in close vessels, a residuary charcoal is always left, which, if wood, compressed peat, and such like bodies be operated upon, possesses the same form as the original substance. The carbon from most kinds of the denser coals does not retain this form, owing to their partial fusion under the influence of the heat, which produces an amorphous mass. Different names have been given to these residues; thus, what is left after the distillation of wood or peat is called *charcoal*, whilst that manufactured from coal is termed *coke*.

Charcoal and Coke.—The preparation of both these substances has become an important manufacture, as well for the sake of the by-products which are obtained in the operation, as for the carbonaceous matter itself. Carbon in some convenient form is of vast importance in the industrial arts, where great local heat is required. It has been already shown that this high temperature cannot be attained with the use of such substances as contain oxygen and hydrogen in definite proportions, since much of the heat which is produced by the ignition of such materials is necessary to disengage the volatile bodies to which they give rise, and when these are liberated, the combustion is only partial; besides, the caloric which results in this case cannot well be

concentrated, and cannot be rendered very efficacious by radiation. It is only charcoal, and such bodies as will develop the greatest amount of heat from the smallest possible extent of surface, that can be employed with advantage in such operations as the smelting of metals, especially iron, and for the purposes of railway transport, *et cetera*.

Not only is carbon valuable as a fuel, it is likewise highly serviceable in many other respects; its uses, as a disinfectant, have been given in Vol. I., p. 563; it is likewise employed as an absorbent of many gaseous bodies, for depurating sirups and extracts, and as a manure. It is chiefly, however, in connection with its application as a fuel, and its superior heating effects, that the various methods of preparing it will be here detailed.

Carbon, of which charcoal, coke, *et cetera*, are modifications, is known in its native purity in the diamond, although, as may be supposed, the quantity of it found in this form is very small. The Ghauts in India, more especially Golconda, Borneo, and the Brazils, furnish this precious gem. In this state it possesses remarkable transparency, brilliancy, and hardness, to such a degree that in no one of these attributes has it a compeer. Its specific gravity is 3.336; it may be burned in an atmosphere of oxygen gas, or in the air, under the influence of a very high temperature, when it is converted into carbonic acid; and ROGERS, by acting upon it in a finely divided state with bichromate of potassa and sulphuric acid, found that it is completely converted into this gas. With a Bunsen's battery of one hundred plates, it may be fused into a mass resembling very compact coke.

A charcoal approaching the diamond in purity, though partaking of none of those qualities which render the latter so valuable, is prepared by heating non-nitrogenous matters, such as sugar, dextrin, and the like, to redness in close vessels; or by passing the vapor of alcohol, ether, or some carbonaceous oils, through tubes heated to whiteness. In either case, a very pure form of carbon is left. As obtained by the latter process, charcoal is a brittle, black, insoluble, inodorous, and tasteless substance, capable of conducting electricity with freedom, but obstructing the passage of heat in a remarkable manner. It is unaffected by air or moisture, a quality taken advantage of in the construction of charring piles, so that they may resist the bad effects of moisture; also, in scorching the interior surface of casks and barrels destined for holding water and such liquids, both that the contents may be preserved wholesome and pure, and that the soundness of the vessel may be secured. In a pure state, it is infusible, or only fused in a slight degree by the greatest known temperatures. As stated in Vol. I., p. 563, it absorbs many gases in large quantities, has the quality of removing many alkaloids and bitter principles from their solutions, and latterly has been introduced by Dr. STENHOUSE as a physico-medical agent.

PROCESSES OF CARBONIZATION.—It is known from ancient records, that the manufacture of charcoal from wood has been practised for more than two thousand years; and very little progress appears to have been made, till lately, in improving the process. Many obvious circumstances would concur to induce the

carbonization of wood in early times, such as the trouble of carriage, and the facility of charring it on the spot where it was felled. It has been shown that wood, by drying, loses sometimes as much as forty to fifty per cent. of its weight; it also contracts in proportion, and if the heat be carried on to the point of charring, this contraction will reach to twenty or twenty-five per cent. of the bulk: hence the advantage obtained by this process in point of carriage. The system followed was such as to require partly the intervention of the air, and involved the destruction of a portion of the woods; the loss being greater or less in amount, according to the care bestowed and the precautions taken. The old course is still adhered to, with some slight modifications. Taken in connection with what has been already said as to the effect of heat upon wood and matters of an analogous composition, the following remarks may suffice to point out how far the admission of air and the application of an increased temperature affect the production of charcoal.

It is evident that when a piece of wood is ignited, the heat which destroys its elementary composition passes gradually inwards from the surface, till the whole is permeated, and as each successive layer of fresh fibrous matter is attacked, the volatile compounds resulting from the oxygen and hydrogen of the substance will issue at every pore, thus producing a mixed atmosphere of aqueous and inflammable matters around the wood. The combustion of these without the surface of the solid matter prevents contact of the latter with the oxygen of the air; hence, as long as they are formed, the charcoal which is left after the decomposition of each successive layer of lignin remains intact. It is different when they cease to be developed, for then the oxygen of the air is admitted, and the temperature being sufficiently elevated to induce combination, the charcoal rapidly decreases, so that, if the oxygen continue to be supplied, nothing will be left but the small quantity of mineral matters contained in the wood.

So long as the action of the heat supplied is restricted to the first stage, the results will be satisfactory; but when it enters upon the second, inconvenience and loss are occasioned. In the common process it is impossible to exclude the air altogether, as the charring of the

main bulk is effected through the agency of the complete combustion of a portion of the same material in the mass; nevertheless, by regulating the quantity and direction of the current, much of the loss incidental to this method would be avoided. For instance, in the carbonizing of two pieces of wood, of the same state of dryness and

at A, while the ignited end of the other is averted from the blast, as at B—Fig. 17—it will be found that the first of these will be speedily consumed, whereas the other, the charred portion of which is partly protected by the gases disengaged, disappears much more slowly, and sometimes leaves a residue of charcoal. Were it possible to introduce, as the distillation progressed, the parts of the second sample which was charred, into a tube or vessel where it would be excluded from the air, a much larger amount of charcoal would result. Hence it may be inferred, that in charring heaps of wood with a movable coating of mould covering it from the air, the current should be led from the furthest and coldest extremities, that the gases, as they issue, may protect the matter already decomposed from destruction; and again, that the best course would be to effect what is termed the destructive distillation of the wood, keeping the matter subjected to this process entirely out of contact of air. Such a process of decomposition may be carried out in close vessels, and this is the one best calculated to afford the largest yield of charcoal; besides, by a little additional care and management, the various other constituents of the matter operated upon and modified, so as to exist in states which are more or less valuable in other applications, can be recovered and turned to profit.

Notwithstanding that by the process of destructive distillation in close vessels, the greatest possible control is exercised over the operation; still, if the resulting charcoal be compared with the content of carbon in wood, it will be apparent that a considerable loss is sustained. According to the analysis of the samples of wood already laid before the reader, it would appear that if the elements of oxygen and hydrogen, which exist in all of them in nearly the same proportion as in water, were removed, the charcoal remaining should constitute from thirty-eight to forty, or even forty-five per cent. of its weight, but in actual workings the yield is often so low as fifteen to twenty, and under the most favorable circumstances only twenty-seven to twenty-eight per cent. of the wood are obtained. The difference between the practical yield and that which theory would indicate, is, in these cases, considerable, and is accounted for by the circumstance that the water, which is formed at a certain temperature, reacts upon the remaining charcoal, and, according to the degree of caloric which it possesses, occasions the formation of several other compounds—such as those mentioned in the two previous pages—all of which are rich in carbon, deriving this from the charcoal, to the loss of the manufactured product. These different forms of combination proceed in the order of their oxidation, the richest in oxygen being given off first, and being succeeded by others containing less of this element, till, at the conclusion of the distillation, nothing is left, and the final products are composed of carbon and hydrogen. Thus, in exposing wood to heat in close vessels, the first bodies that are observed to pass off are water and carbonic acid, followed by acetic acid and carbonic oxide. These are succeeded by a highly carbonaceous oil of a deep brown color and empyreumatic odor, which contains but little oxygen, and, lastly, carbides of hydrogen. As

Fig. 17.

having equal dimensions, in a current of air, to which the lighted extremity of one of them is presented, as shown

long as oxygen is in abundance, the latter are not generated, and also they cease in part to exist when the temperature is very high, as the oil and acetic acid are incapable of resisting a high temperature without being mutually decomposed, and resolved into water, carbonic acid, and carbide of hydrogen. The more oxygen and hydrogen that can be abstracted from the wood in the shape of water, the greater will be the bulk of charcoal left; and to insure this the best course is to apply a heat which is only sufficient to cause the combination of those elements, although inadequate to produce the other products of a higher temperature.

The course sometimes adopted, of submitting wood which is much saturated with moisture to the action of heat, for the purpose of charring, is disadvantageous, because the vapor of this body, passing over portions already charred and partly incandescent, transforms them into carbide of hydrogen—CH—and carbonic oxide—CO—and thus diminishes the yield of solid matter; indeed, if this decomposition were thoroughly effected, there would not be as much material as would supply carbon for this end. Woods, therefore, which are treated for the purpose of obtaining the largest amount of carbon or charcoal from them, ought to be well exsiccated, so as to be divested of extraneous moisture, and then the temperature should be so controlled that the material will not attain a red heat, for, under the

latter circumstances, the water produced from the elements of the wood would react in the manner above mentioned, to the detriment of the operation. M. KARSTEN made some experiments, with the view of ascertaining the relative effect of a low and high temperature, and found that if chips of wood are exposed for a long time to a heat of 300°, they will ultimately cease to lose weight. The loss sustained when air-dried wood is so treated amounts to sixty-five or seventy per cent., but when the material is first desiccated at the temperature of the water-bath, the utmost limits are from fifty-six to fifty-nine per cent. The residue in either case resembles charcoal in appearance, and was regarded as such by RUMFORD, who considered it as the skeleton of the plants; but KARSTEN has shown that it is but a modification of woody fibre, still holding matters which, when subjected to a high temperature, pass off as gases. However, the product from the application of a high heat is very different from that obtained when a low progressive one is applied, as shown by the results of KARSTEN's experiments in the subjoined table, to which are annexed the numbers given by STOLZE and WINKLER. The wood taken as the subject of experiment by KARSTEN was dried in air, and that which WINKLER operated upon was exsiccated in a hot room, whilst STOLZE torrefied his at 212°.

TABLE SHOWING THE PRODUCE OF CHARCOAL AT HIGH AND LOW TEMPERATURES:—

Species of Wood.	By the quick process of charring		By the slow process of charring.

Cane Stems,	14.65	26.45		

It will be observed at a glance that the advantage of a slow process of carbonization in regard to the production of charcoal is in some cases double, and is, therefore, so profitable in this respect, as to warrant its being resorted to upon all occasions. A slight difference exists in the proportion of charcoal which many of the woods in the foregoing table afford, although the same course was followed in their carbonization. The probable causes of these variations are, the changes of temperature which are liable to be experienced even within short periods in the course of manufacturing processes; and agreeably to this sup-

position, the widest range will be found between the results obtained at the high heat, where the variation was more likely to exist than in those samples charred at a low temperature. Taking the numbers in the second column of KARSTEN's results as the maximum quantity which it is possible to obtain on the large scale, and comparing them with those which are arrived at by manufacturers who distil wood with the greatest precaution in close vessels, and who have in view the utilization of all the products resulting from the operation, this remarkable coincidence will be apparent. The general results obtained by these manu-

facturers may be expressed thus for one hundred parts of wood :—

Charcoal,	28 to 30
Acid and water,	28 to 30
Tar,	7 to 10
Carbonic acid, carbonic oxide, carbide of hydrogen, and uncondensed water,	37 to 30

If to these numbers the weight of wood necessary to effect the distillation, and which is generally about twelve and a half parts, be added, the results will agree well with what is arrived at in practice in burning for charcoal. In air-dried wood containing about forty-five per cent. of carbon, this element is distributed in the following manner :—

Charcoal left as residue,	30.00
„ combined in the form of acetic acid,	0.50
„ „ in the state of tar,	6.00
„ „ as carbonaceous gases,	3.50
„ required to effect the distillation,	5.00
	45.00

These results agree as closely as can be expected with the numbers given by theoretical calculation, assuming that there is no further disturbance of the elements beyond the union of the oxygen and hydrogen to form water, and the evaporation of this body together with the heating of the remaining charcoal to incipient incandescence, or to about 932° Fahr. Making these conditions the basis of the calculations it is found, theoretically, that to form the water from the elements in 112.5 parts of wood, and to dispel it together with the moisture in combination, which amounts to about sixty-seven and a half parts, the heat developed by the combustion of six parts of charcoal is necessary. Proceeding in the same way, it is found that to bring the residuary charcoal to the above-mentioned temperature, about 0.77 parts are required, making in all 6.77 parts. Practically, only five parts of charcoal are burned to perform this work; but, unfortunately, much of the carbon is carried away in the gases, so that the last number swells to eight and a half or nine parts of charcoal in the charring of the quantity already named. Even these figures are close enough to those deduced from theory to warrant the inference, that in the charring of wood no very considerable improvement towards producing a larger yield of carbon can be made upon the common method, by which from twenty-five to twenty-seven per cent. of the weight of the original substance is obtained.

Having thus far enlarged upon the theory of the subject, the practical operations will now be considered. The distillation of wood has already been explained under ACETIC ACID, though chiefly with reference to the production of the latter body. It is now to be considered with special reference to the yield of charcoal; and with this object in view, there are several methods of procedure, all differing, more or less, in their practical details, though they may all be classified under two methods, namely, such as require access of air, and those in which the air is excluded. The former includes all the different methods of charring in mounds, to which preference is generally given, to avoid the cost of transport. In purchasing wood for this purpose, its weight is estimated in a rough way in the cutting, and

an approximate valuation of the timber, the charring wood, and brushwood, is made by ocular survey. To assist in this, tables have been drawn up to indicate the probable yield of charcoal from the variety of wood, according to its solidity, and the nature of the principles contained in it. The value of wood, as thus ascertained, is liable, however, to be affected by various causes—the difficulties in working it, the badness of the ways through which it is to be transported, and the conveniences which the locality offers for constructing a mound. In France, the price of a cord of wood consisting of seventy cubic feet is, on an average, from six to seven francs, or five shillings to five shillings and tenpence, but in the province of Champagne, where iron-works abound, the rate is higher. The purchaser of the wood usually cuts it, when too large, into suitable lengths, either by the hatchet or the saw; these lengths are about two feet when the material is to be charred in stalks, but when this process is to be carried on in heaps the logs are left about seven feet long. The workmen engaged in this business are paid from seven to ten pence per cord for cutting, and two or three pence for piling. Sometimes the wood is carbonized immediately, but generally it is left to dry for a certain period. Although the latter method is attended with an increase of interest on the outlay, still the quality and yield which the dried wood affords is more than adequate to repay this.

The site of the mound, or *meiler* as it is termed on the Continent, is carefully chosen by the charcoal maker. Some spot is generally selected which is sheltered either by a declivity or a wood from currents of wind, and at no great distance from the felled timber. The soil must be neither too damp nor very dry; in the former case, the moisture evaporated by the heat and passing over the charcoal, would at the high temperature convert much of the solid into gaseous bodies, and so occasion a loss; and in the latter, currents of air would enter through the interstitial channels, and prove as injurious as the humidity, or even more so. A spot which inclines to neither of these extremes is carefully cleared off in the summer time; and previous to erecting the meiler, if any misgiving is felt as to the fitness of the site, it is covered over with shingle or planks, and these are overlaid with charcoal powder to the depth of several inches. Having thus prepared the flooring, a stout stake is erected in the centre, having its upper end cleft crosswise at right angles; and into these incisions two logs are adjusted, forming right angles with one another in the same horizontal plane. Four logs are then inclined against the vertical post, the upper ends fitting into the angles produced by the intersection of the cross bars at the top. The floor or hearth of the meiler is then formed by placing billets of wood all round, radiating from the central post; the vacant spaces are filled with pieces of wood of smaller dimensions; and to secure the whole in the order in which they are laid, pins are fixed all round the periphery at about a foot distant from one another. Very dry wood, or such pieces as are easily ignited, are now arranged around the central post in a nearly vertical position, so as to form a truncated cone; these are enclosed by layers of billets of about equal length placed

horizontally on the floor, and the vacancies filled up as before. Two or more such layers, forming concentric rings, are added to increase the diameter of the mound, as shown in the sectional drawing, Fig. 18;

Fig. 18.

and these, as they are successively raised, incline at the same angle as the nucleus around the central stake, owing to the logs being all cut of the same length, according to a regulation enforced by the Forest Laws. This is advantageous, inasmuch as it offers facilities for covering the whole more firmly with the soil or mould. When raised to the proper height, the heap is rounded at the top by adjusting logs and brushwood together; and after this the whole is coated with a covering of soil from four to six inches in thickness, interposing grass, leaves, and such bodies between it and the wood. This coating does not extend to the bottom, but rests upon a layer of twigs and branches a few inches in thickness, held in their position by forked uprights—an arrangement adopted to allow of the escape of the aqueous vapors which are discharged by the first action of the heat upon the wood. Were the steam permitted to escape at the superior openings, too much draught would be produced, and more air would thus be admitted than is advantageous to the working. The base of the meiler is protected from unfavorable draughts by an armor of wicker work—as seen in Fig. 19—representing the heap ready for ignition. In this

Fig. 19.

drawing, *a* denotes the quandel, *b* the aperture by which the mass is ignited, and *c* and *d* the armor surrounding the base. A few holes are left in the top and sides of the heap corresponding to the billets

placed at the base. Care is taken to have the cover much more solid at the top, in proportion to the height to which the meiler is raised, so as to resist the draught which chiefly exerts its influence on this part of the heap. The mass is ignited by adding glowing charcoal to a quantity of brushwood which is placed in a channel left at the foot of the meiler for the purpose; the fire rapidly traverses to the interior and attacks the logs which are arranged round the vertical stake; when these are red-hot the upper orifices are closed, and the first stage of the operation, namely, the *sweating*, is then allowed to proceed. Much care is required to prevent a too copious disengagement of vapor at this period, which would destroy the heap; the process is going on well as long as the smoke presents the appearance of a yellowish-grey cloud. Much watery vapor is emitted at this stage, portions of which condense upon the covering of the heap, giving it the appearance of exudation. As the moisture is expelled the gaseous matter assumes a lighter grey appearance, which is the indication of the second stage of the process. The wood of the stake and portions of that surrounding it are now consumed, as well as the brushwood at the top; irregularities are, consequently, formed in the covering owing to portions of its support yielding, and openings for the escape of the products of the combustion are produced. About this period the aperture which was caused by the annular support at the base, termed the *armor*, is closed; after this, and on observing the above indications, the top part of the covering is removed as speedily as possible, the logs near the stake broken up and forced together with a long pole, and the empty space thus formed charged anew with more logs, the whole being secured under the mould as before. The entire combustion of the portion of wood in the centre, and of the smaller branches throughout the heap, now reacts upon the remainder of the logs causing their destructive distillation.

For several days the charring proceeds progressively towards the exterior of the meiler. During this time continual attention is necessary, as well in allowing the tarry vapors to issue at the base by making openings for that purpose, as in supplying air for maintaining the heat required for the charring, and checking the draught where the temperature and the combustion are too violent. As the work progresses and the wood becomes charred, the heap contracts, but this is apt to be very partial unless the workmen control the draught, by making outlets in the covering of that portion where the effect of the fire is slow, and drawing the heat to it, at the same time putting on a thicker coating where the action is likely to be too vigorous. Having done this in the upper part of the heap, it still remains to conduct the heat to the outer surface. The cooling tendency of the coating, and the condensation of water and empyreumatic matters upon it, render the ignition of the logs near the coating impossible under the circumstances hitherto stated; and if the operation were allowed to proceed, the logs in the outer ring would be only half or three-quarters burned, even when the charcoal in the interior would be overdone. To guard against this, a second series of holes must be made in the upper part of the breast of the meiler, in a line

with those at the foot, but more distant; these openings need not, however, be made as high as there is wood uncharred, for the direction of the draught to this quarter will generate as much heat as will be sufficient to carbonize it, even above the temporary chimneys. From these orifices a thick black smoke is discharged, which, after a time, is succeeded by a thin blue cloud; as soon as this is observed the orifices made are closed, and others formed at a distance of two or more feet nearer the base, and the vapors allowed to issue by them till the same appearances are observed as before. According to the size of the heap and the state of completion of the work in hand, a third and fourth series of such perforations are made in the covering, and the combustion of the matter in their vicinity is allowed to proceed till the heat is intense enough to decompose their elementary arrangement, after which they are closed. When the process is finished, flames issue simultaneously from the different apertures around the heap; and should this not be general, vents are opened in other parts in order to expedite the appearance of the flame all round. When this occurs, the process is completed, and the duty of the attendant is now to extinguish the incandescent mass. Were this point overlooked, and the heap broken up before the charcoal was thoroughly cooled, no inconsiderable loss would be sustained; on the other hand, if it were left to part with its caloric spontaneously, too long a time would be required for this purpose, in consequence of carbon being a bad conductor of heat. The course adopted is to coat the whole heap with a thick layer of moist earth, and to leave it thus choked during a period which varies according to circumstances—generally twenty-four hours; if the temperature be not sufficiently reduced by this time, as much of the covering as is possible, without exposing the charcoal to air, is taken away, and replaced with another layer of the humid soil. If two coverings be given, the time allowed for its remaining on the heap is shortened.

When the whole is sufficiently cool for drawing, the covering is stripped off, and the charcoal taken and spread upon the soil in a thin bed; should any sparks remain, it is necessary to exclude the air from these parts by throwing sand upon them. Another method is practised, which, though more expeditious, is nevertheless more open to loss. It is to strip the meiler partly at the base, and by means of a hook to draw out the logs of charcoal separately and cover them instantly with sand, clay, or some such material as will readily extinguish them; water, when convenient, is employed for this purpose. When as many logs are abstracted from this opening as can be easily managed, it is quickly closed so as to prevent, as far as possible, the combustion of the incandescent charcoal; a fresh hole is then made at some distance, and the charcoal taken from it treated as before. This operation is repeated all round the base of the meiler till the whole is extinguished. Night is the best time for conducting this part of the work, as the darkness enables one to observe the smallest spark in the charcoal.

In the methods adopted in the New Forest, a different arrangement of the wood in the construction of the

meiler is resorted to. The logs are placed perpendicular, or nearly so, around the central stake, or quandel, to the breadth of the pile, and one or two other rows, all in an erect position, are superimposed upon this; the top of the stack is rounded by fixing shorter logs horizontally, in the manner indicated in the sectional drawing—Fig. 20. In all the other details the

Fig. 20.

working of both forms of meiler is the same, differing, however, in the manner of igniting. With the arrangement here represented, the fire is communicated from the top. The quandel being formed of three stakes fixed at the distance of a foot from one another, at which distance they are retained by introducing blocks of wood between them, the empty space is filled up with dry brushwood and half-burned charcoal. Combustion is commenced by introducing red hot coals into this part, and as fast as the light wood is consumed fresh material is supplied, until the logs of the meiler have in part undergone combustion. The regulation of the draught is attended to with all possible care, and so conducted as to induce the carbonization of the wood after the sweating, in the order represented by Fig. 21.

Fig. 21.

To effect this the draught must necessarily be directed from the burnt towards the unburnt portion. This is managed by forming the temporary chimneys in such positions as to draw the volatile matter from traversing the burnt portion, while the openings at the base are at some distance from that part where combustion is taking place. The effect of the fire is known by the depression of the covering, and this apprizes the attendant where the openings for the draught should be made, so as to keep it from that portion which is already carbonized. In the latter method of constructing the pile, care must be taken not to allow much vacant space between the logs, especially between the ends of the first range and those of the next. If this were neglected, the circulation of air would be too

rapid, causing the fire to spread over a large surface without effecting a sufficient carbonization.

Both these forms of meiler are used generally in the forests, and perhaps it is difficult to say which is preferable. Among the Swedish burners it has been established that more charcoal is obtained when the logs are piled up horizontally, than when they are arranged in a nearly vertical position; but the charring is not so well or so readily effected. With the second or vertical method, the loss by combustion is much greater, but the quality of the charcoal produced is superior to that obtained by the other processes.

Another method of charring is in use, especially at Wienerwald, and also in mountainous districts where there is no great depth of soil, and where resinous wood is operated upon. The form of the heap or pile is shown in Fig. 22—a kind of structure termed *Haufenverkohlung*, and offering facilities of charring uncleft wood of every dimensions. When this mode

is adopted, it is customary to bark the wood, in order that the fire may attack it more readily than it would do if not so prepared. The best period for depriving charcoal wood of the bark is immediately after felling, for then the operation is easy, whereas, if attempted when partly dried in the air, considerable difficulty would be experienced. Besides presenting advantages as to facility of combustion, barked wood has other qualities which ought to be taken into consideration by those engaged in the business; especially a greater freedom in parting with moisture, requiring, according to the experiments of AF UHR, only a fractional part of the time usually allowed for spontaneous desiccation. The results appended indicate the advantage in this respect, the experiments being made on pine-wood, in a shed open at the sides, but protected from the admission of the rays of the sun and from rain. The period of the experiments was—

Species of Wood.	From June to				Per centage of original weight.
	July.	August.	Sept.	Oct.	
Whole logs,.....	0·41.....	0·84.....	0·92.....	0·98.....	}
Logs deprived of bark,.....	34·53.....	38·77.....	39·34.....	36·62.....	

From these numbers it may be inferred, that by using barked wood a vast advantage is gained in point of return of capital, as the quantity of water which is evolved from the wood so prepared is only what the same quantity of timber would lose, how long soever it might be left air-drying.

Heaps of a rectangular form always afford less charcoal than the meiler process, but the loss is in some

where it measures from nine to fifteen feet, according to its length. A small recess is allowed in the lower extremity, as seen in the figure, for the purpose of lighting, when the arrangements have been made for that purpose, and the heap is well covered with moistened charcoal or mould, and beaten as solid as possible. Fire is placed in the chamber just mentioned, and the small wood contained in it quickly undergoes combustion; a draught is instituted by making several holes in the front of the heap, at a distance of about fifteen inches from the level of the ground. As soon as the fire takes hold on the wood of the heap, the first opening is securely closed, and others opened along the front, so as to draw the heat along the base which is being charred, whilst the upper part is undergoing the sweating stage. When a light smoke of a bluish tinge issues through any of these openings, the attendant knows that the charring conditions are favorable in those parts, and that it is time to conduct the draught to other quarters, and for this purpose the openings already made are closed, whilst others are pierced in the covering at a proper distance. After the fire has traversed the entire breadth, the draught is still maintained by making perforations in the sides of the heap near the ground, and corresponding ones in the upper surface of the mound, taking care that the current thus instituted traverses only where the wood is undergoing distillation. The practice is to draw the charcoal from that part of the heap which has been charred, as soon as the fire has extended as far forward as the heap is wide. This is continued partly throughout the operation, but so sparingly, that about half the heap will be left when the more bulky end comes to undergo active carbonization. The necessity of covering all the parts, and of sprinkling the surface of the heap with water to allay the heat in some degree, should not be overlooked. When this method is successfully conducted, the fire traverses about a foot and a half daily, causing

Fig. 22.

measure redeemed by the circumstance, that the operation is more easily conducted in consequence of the vents and draught-holes being more under control in this than in the conical form. The site generally chosen for the heap is a gently inclined plane, about seven to ten feet in breadth, by thirty to forty in length. Posts corresponding to the intended height of the heap are fixed vertically around this space and about two feet apart; to these boards are nailed so as to retain in its place the covering of mould or powdered charcoal, as the case may be; sometimes wicker-work is substituted for boards. The logs of wood are now placed transversely to the length of the parallelograms, taking care to have the larger ones at the base, and to fill up with lesser wood all the intermediate spaces; sometimes, however, they are arranged lengthwise. As the heap increases, the upper surface is made to present a cuneated shape, by heightening the anterior part, and gradually tapering to an angle of 15° to 20° with the horizon. When finished, the heap is no more than two feet in height at the front, whilst it increases gradually to the opposite end,

the operation to last for a time proportionate to the length of the heap. According to DEBETTE, the product from 35·3 cubic feet—one stère—is

In large charcoal, 27·44 cubic feet.
In small charcoal, 0·95 “

Making a total of 28·39 cubic feet, weighing about 185 pounds.

This product is much less, however, when the smaller kind of wood is employed.

The commoner and less economical methods of charring have now been noticed, but the demand for the charred article, as well as for the substances which the dry distillation of wood affords, has tended to induce a modification of the processes, with the view of enabling the charcoal-burner to obtain a larger amount of charcoal than is possible by the methods just described, and also to recover considerable quantities of the products of the decomposition of the wood.

In the first of these deemed worthy of notice, the main features of the meiler are retained, but by enclosing it in sheds, which may be of wicker-work or of boards, the destruction of a portion of the wood from exposure to the wind is prevented. In the construction of this kind of covering, the advantages of its being portable and easily adjusted are obvious; hence it is generally made in divisions which are readily connected with each other, so as to form a complete shed round the pile, large enough to leave an interval of a few feet between. An opening is made at the top, for the escape of the smoke and gases, and another at the side, temporarily closed with a curtain, for the ingress and egress of the workmen. Sometimes the walls of this shed are made of solid materials, such as stone, bricks, *et cetera*, and roofed by planks or stout boards, leaving sufficient room between them for the smoke to escape. By this arrangement, the results of the carbonization are increased to twenty-two per cent. of charcoal.

Another modification of the meiler process, suggested by BRUNE so far back as 1801, and which was examined and reported upon by BLAVIER and BROCHIN, is said to expedite the charring, as well as to increase the yield of charcoal. The heap is in this case constructed, where the meiler is stationary, by digging a circular hole to the depth of a foot, and depositing a frame composed of bars of iron, upon which is laid a cover constructed of sheet-iron plates well riveted, and of the same area as the base of the heap. Instead of excavating the soil, an annular wall of brickwork or masonry may be built, with internal supports for the base. Care is taken to have the plates air-tight before the meiler is formed upon it; this is tested by introducing a few lighted faggots at an opening which is left at one side, and which forms a kind of hearth, and observing if any smoke issues through it. Air is admitted for supporting the combustion of these faggots through three other apertures, one of which is opposite to the hearth, and the others equidistant from it. The meiler being erected and covered, first with brushwood and foliage, and finally with moist powdered charcoal, five or six burning faggots are introduced beneath the plated base at the

hearth, and the combustion is kept up with fresh quantities for about an hour, when the whole base of the meiler will be in a state of ignition. At this stage the vent-holes and the hearth are closed, and other openings made in the usual manner in the covering of the mass, closing them as combustion becomes sufficiently advanced.

The superiority of this mode is attributed to the greater conducting power of the metal than of the soil, by which the heat is distributed so rapidly as to cause the ignition of the whole of the wood in contact with it in a very short time, and without the necessity of admitting any increased volume of air. Nor is it necessary for effecting this, that the whole of the base should be heated; an area of five feet will be sufficient to communicate a decomposing temperature to a meiler of thirty feet diameter at the bottom.

Upon the same principle, although less effective in charring the wood quickly, is the plan of erecting the meiler upon a stationary foundation, so constructed as to yield a portion of the products of the distillation. Fig. 23 represents this bed vertically, and Fig. 24 its elevated section. The structure is built of bricks, and has an inclination either from the circumference to the centre, as shown in the drawings, or reversely. In the former case, the centre of the bed is hollowed perpendicularly, and from the well thus formed, an outlet leads to a brick tank at the side. The central well is represented in the drawings by *d*, the channel by *b*, and the tank by *c*. The well is covered during the carbonizing with a perforated grid to prevent its being filled with the charcoal, and care is taken not to allow the ingress of air through the channel. This method is followed for the most part in the Landes, in Pologne, and in Russia, and where resinous woods are at hand; it is designated the distillation *per descensum*, from the circumstance that the tar, resin, and such heavy products fall through the heap, and flow into the tank *c*, where they are recovered.

Of the various methods of carbonization which chiefly aim at obtaining the greatest amount of charcoal in the readiest way from a given weight of wood, the mode followed in America seems the most advantageous. Not, indeed, that this materially differs from the European systems, or that it does away with the necessity which is involved of consuming part of the material, but that the loss which is unavoidable is confined to matter which has less value than the charcoal. With this view, the interstices of the meiler are filled with powdered charcoal, which, by burning, gives out so much heat as to effect the rapid distillation of the wood, whilst, at the same time, it preserves the carbonized material from contact with the air. By this process it is said that about twenty-two per cent. of charcoal are obtained, which is clean to the touch, and

Fig. 23.

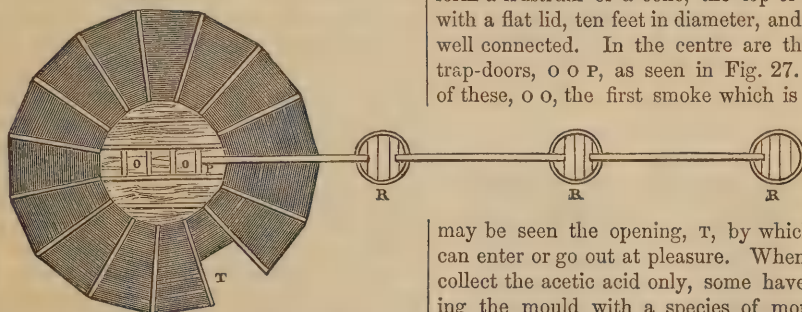

Fig. 24.

in every respect similar to that produced by the distillation of wood in close vessels.

Such are the improvements which have been effected in operating with the ordinary meiler, having no regard to the perfection of the process by turning to profit all the products afforded by the wood; but, from the number of these, and their utility in the arts, their waste could not be long permitted, especially when their value became known. To submit the wood to distillation in close vessels, however, would involve a considerable outlay in costly apparatus, which at the same time would fail to furnish a quantity adequate to the requirements of the trades which consume it, and hence more simple, as well as more effectual methods were a desideratum. The conditions required were, to a great degree, fulfilled by the processes proposed by FOUCAUD, BAILLET, and SCHWARTZ, but others have been suggested and acted upon.

FOUCAUD's method, which is the simplest of these, is founded on the principle of sheds; all the other details being much the same as in the common *pile* process. A covering is provided, which, while it affords all the advantages derived by the use of sheds, adds

Fig. 27.

meiler being ignited passes out; and after this the condensable products are drawn off through the third opening by a pipe bent at right angles, and conducted into the first of a series of condensers, R R R. This arrangement is shown in elevation in Fig. 28, where

Fig. 28.

the decomposition of the contents. It is constructed by digging a circular cavity in the earth of any convenient depth; or, where this cannot be done, building a mould wall round the space corresponding to the size of the furnace. When sunk in the ground, holes are made perpendicular to the base, and at a distance of a foot from the facing of the wall of the cavity; they are made to open inwards at the base. In the other form, the perforations are fixed at the base to open inwards in the same way. Fig. 29 represents this kind of carbonizer, half in plan and half in elevation, and Fig.

the means of collecting the volatile products in suitable condensers; and to render it more efficient, it is so made as to be simple and economical—the diameter of the base being thirty feet, at the top ten feet, and the height eight or nine feet. To form this shed, frames twelve feet long, three broad at one end, and one foot at the other, are constructed of bars of wood two inches square. Upon these, stout twigs in the form of wicker-work are woven; wooden holders are attached to each frame, by which, and the use of an iron or wooden pin, they may be joined together. Before putting them up, it is customary to coat them with a well-tempered

Fig. 25.

Fig. 26.

loam, with which some chopped grass is mixed. Fig. 25 shows one of these frames, and Fig. 26 one side with the holders appended.

When a number of these are adjusted together, they form a frustrum of a cone, the top of which is closed with a flat lid, ten feet in diameter, and made of boards well connected. In the centre are three openings or trap-doors, O O P, as seen in Fig. 27. Through two of these, O O, the first smoke which is evolved on the

may be seen the opening, T, by which the workmen can enter or go out at pleasure. When the object is to collect the acetic acid only, some have proposed coating the mould with a species of mortar made with quicklime; the acid unites with this base, and forms acetate of lime, which may be treated as indicated under ACETIC ACID.

BAILLET's form of carbonizer, reproduced with various improvements in the apparatus of M. LA CHABEAUS-SIÈRE, consists of a cylindrical chamber, covered with a plate of cast-iron, and furnished with orifices, for the admission of air to support the combustion of a portion of the wood, and also for the passage of the products of

30 a section of the same. In the first of these, A denotes half the plan at the level of the base, and B the other elevated portion under a vertical view. The same are seen in section, where C indicates the half section over the chimney, and D the half over the air-channels.

The bottom of the furnace, E, is constructed of refractory clay, well beaten, or of bricks; so also are the side openings, G, of the air-channels in the bottom. F F indicate the mouths of these holes, H is the brick-chest or pipe for conducting the smoke, and I the casing of

the same material upon which the verge of the lid rests. This most important part of the furnace is constructed of wrought-iron plates, bound by clamps or

Fig. 29.

hoops of sheet-iron. Its form is a segment of a sphere, its diameter is ten feet six inches, being six inches wider than the pit, so that it will rest three inches over

Fig. 30.

the edge of the wall. It ought to be sufficiently solid to bear the weight of a man without being injured. A perforation, *a*, Fig. 31, is made in the centre; this opening, which is nine inches in diameter, and closed by a movable plug of iron, serves as a vent for inducing

Fig. 31.

the ignition of the wood, as well as for introducing red-hot coals for that purpose. There are four other openings, *b b*, equidistant from each other, and six inches from the rim. The diameters of these are only four inches, and they are intended as draught-holes for the escape of the first heavy vapors that are given off when combustion sets in. In diameter the furnace is about ten feet at the base, being a little more at the top, and it is nine to nine and a half feet in depth. About six inches thick of solid flooring, composed of refractory clay, is laid on the bottom, bringing this up to the level of the inlets. It should be well beaten, in order that it may the better resist the heat, as should likewise be that of the walls of the furnace. The air-

holes are generally about two to two and a half inches in diameter, though openings of a less calibre would be sufficient; but by placing a tile upon the orifice, the volume of air may be reduced at pleasure.

The outlet through which the volatile products pass is introduced at about nine inches below the ledge of the furnace; it is nine inches in diameter, and inclines towards the body from the further end, which abuts in a rectangular box, eighteen inches in length, twelve in breadth, and fifteen in height. During the distillation, tar and portions of the acid condense in the box, the walls of which are made of brick, the cover being a movable plate of iron; and when nearly filled, or in such a state as that it would obstruct the passage of the vapors, the excess is drawn off by a stopcock in the side near the bottom. A cast or wrought iron pipe is fixed vertically in the lid of the box, and at the height of about four feet it is bent horizontally, or slightly depressed; the horizontal part is about fifteen feet in length, so that the contents may be cooled during their passage, and prevented from spontaneously igniting. The far end of this pipe discharges itself into a wooden sluice or covered trough, which conducts the products into suitable condensers. Before putting the furnace in operation, it must be well dried by lighting some brushwood, and keeping up the heat till the bottom and sides are thoroughly baked. The charging is commenced by fixing a round stake four inches in diameter in the bottom, and of the same height as the furnace. Around this, some charcoal is placed to keep it upright, and then logs of wood are arranged horizontally, radiating towards the circumference and between the air-holes, observing that the ends reach neither to the central stake nor to the wall of the furnace. The spaces unoccupied between the radii, form so many flues from the draught-holes to the centre. Another layer of logs is laid transversely upon these spaces, and close to each other, thus leaving as few vacancies as possible. Other layers are placed upon this successively till the furnace is filled, and all the spaces round the circumference are charged, either by alternating the logs, or by employing smaller wood for this purpose.

The next step is to withdraw the central shaft, and to fix the cap in its place; the latter operation is facilitated by the use of two iron levers and wooden rollers twelve feet in length, which pass over the furnace and rest on the ground at each end. All the openings in this cover are left free, and the remainder is coated with a layer of loose dry earth or sand, two inches thick, in order to cause it to be as retentive of the heat as possible. The draught-holes round the circular wall of the furnace are likewise opened. At this stage, some red-hot embers are poured down the central vent-hole through a kind of funnel, and these falling through the space previously occupied by the stake, which acts as a kind of chimney, come in contact with the combustible material at the bottom, which is soon ignited. For the purpose of diffusing the flame over the contents of the furnace, the central orifice is closed as soon as the fire has acquired sufficient strength. After the bluish smoke which escapes from the charcoal changes to a whitish shade, the draught-

holes in the cover are partly closed, as are also those leading to the base of the furnace; and when the combustion is thought sufficiently brisk, the openings in the cover are entirely stopped, and the vapors allowed to pass off to the condenser. Sometimes the draught produced by the chimney at the end of the condenser is not powerful enough to cause a rapid transmission of the gases and other volatile products from the furnace, in which case the fire is apt to flag or become extinguished. This state of things is detected by the vapors being driven back in the outlets through which they ought to proceed. To remedy the evil, the air-holes at the top of the cover might be opened and a portion of the products allowed to escape, rather than suffer the fire to go out; but the best contrivance is to have a second opening at the top of the furnace, to which pipes may be appended for conducting the gases off to the condenser, but capable of being closed when not required.

The charring generally requires from sixty to eighty hours to produce a good quality of charcoal, but the period is, of course, variable. The attendant examines the state of the interior by thrusting a pole into the furnace through the central opening, and observing if the reduction in the bulk of the mass be equal in all parts. If this be not the case, the draught-hole is opened near that part where the subsidence is least, as also the air-hole opposite to it at the base, and in a very short time the equilibrium is re-established. As soon as the charring is thought to be completed, either by examination with the pole or from the appearance of the smoke which may be evolved, all the air-channels and draught-holes in the cover are opened, with the exception of the central one; a brisker combustion ensues, and some hydrogen which has been hitherto retained is given off. In consequence of this, the charcoal changes from a reddish-brown to a black color, and is so far rendered more marketable. Immediately on the surface of the charcoal becoming incandescent—a state which may be observed by looking through the orifices in the cover—all the openings by which air entered or vapors escaped are carefully closed; the temporary covering on the cap is removed, and replaced by a coating of thin loam. Thus secured, the whole is left from seventy to eighty hours to cool. The furnace is then uncovered for the purpose of removing the charge of charcoal.

It will be observed that the contents at this period possess no more than half the bulk of the wood originally introduced; this reduction arises not from the actual contraction of the matter in charring to that extent, but from the filling up of the interstices by the burned material.

A workman now descends into the furnace and empties it of its charcoal, by taking the pieces up one by one, using as much precaution as possible that they are not broken. The smaller fragments and charcoal dust are removed with a shovel, and collected in a heap together. Should the contents not be thoroughly cooled, the workman employs an iron tool which protects his hands from the heat. Any live or half-burned charcoal which may be present is assorted by itself, then spread out and occasionally raked about, by which it

becomes extinguished of its own accord, and without the use of water; it would be well, however, to have some at hand, in which to immerse any pieces that may be detected burning, which is known by the appearance of white spots. When the furnace is emptied, it is re-charged in the manner already described, and all the operations are repeated in the same manner, and proceeded with as previously detailed.

Five active workmen have been found sufficient to superintend successfully eight such furnaces, working without interruption, and producing on an average twenty per cent. of charcoal throughout the year. The following statement of the work of these furnaces gives a fair average of their annual produce:—

	Tons.	Cwts.	Qrs.	Lbs.	
5000 stères of oak, weighing	123	0	3	16	produced
16,000 hectolitres of charcoal, weighing.....	24	12	0	21	
Impure acetic acid,.....	22	0	0	17	
Yielding upon distillation a purified article, marking 12°					
Twaddell, weighing from	12	15	3	21	
To	13	15	2	14	

The outlay in the construction of each furnace is said to be four hundred and fifty francs, or about eighteen pounds fifteen shillings, of which sum sixteen pounds thirteen shillings are paid for the cap, the balance being ample for constructing the body of the furnace. The condensing apparatus is not included in this statement.

On reference to the article ACETIC ACID, Vol. I. p. 18, the apparatus of SCHWARTZ will be found fully described; and, therefore, any further description of it will be here unnecessary; but something may be added as to its efficiency compared with the others. In localities where there is considerable demand for charcoal, such as in some parts of France and Sweden, where it is largely consumed in smelting operations, the apparatus of SCHWARTZ is better adapted to yield the requisite supply than LA CHABEAUSSIÈRE'S; it likewise answers better for coniferous woods, as the large amount of tar which these yield is most effectually recovered by it. On the other hand, it must be admitted that the wood is more completely charred in the latter, and the time occupied in proportion to the bulk is much shorter; that the cost of SCHWARTZ'S apparatus is much greater, and that it does not admit of removal like LA CHABEAUSSIÈRE'S, except under an outlay as great as the original cost of erection, namely, from eighty to ninety pounds. The advantage of using either of these forms depends greatly upon the facility with which the wood may be conveyed to the melier, as it is evident that, if the distance were great, the cost and difficulties of the carriage of wood over that of the charcoal would more than balance the value of the products of the distillation, and, in fact, of the greater yield of charcoal. In this case, the first method of carbonizing, in large meliers, enclosed in easily movable sheds, will claim a preference to the other two; but sometimes, when the piles are required to be very large, the removal of these becomes more difficult and troublesome; so that their advantages are considered inadequate to the labor, and they are consequently dispensed with. It is evident, therefore, as DUMAS remarks, that in such districts all

the improvements to be made in the manufacture of charcoal must turn upon the better working of the meiler or pile, as being the most applicable; and hence, the first thing to be aimed at is to render this more independent of the cares of the workmen. Upon this, the difference between the pile system and that of distilling in close vessels turns; for, by the former, the most skilful practitioner may be baffled by circumstances peculiar to the operation; whilst, in the latter, the smallest amount of hand labor will always serve to prepare the charcoal, and in the largest quantity.

It is clear that the first consideration on the part of the burner of the pile is the lighting of the fire, so as to spread it over the largest extent of surface in the shortest possible time, and with the admission of as little air as possible. This is usually done by igniting the mass at the base, establishing a draught at the same time from the exterior and through the centre, as seen in Fig. 32, at *p m a*, till the upper parts of the pile are on the point of entering into incandescence. By closing the chimney, *n*, and opening vents at the points, *a a*, around the mound, a draught will be formed through *p m a*. These perforations will in turn be

Fig. 32.

closed, and new ones opened in succession; and as the carbonization advances in *b c* and *d*, care must be taken to bring the force of the combustion in the direction of *p m b*, *p m c*, *et cetera*, so as to char the whole in zones proceeding from the axis to the circumference, and then downwards towards the base. Such is the course which is deemed the most favorable for the charring; but it is evident that this does not include all that is deserving of the operator's attention. An object, indeed, of primary consideration, is to render as much as possible of the caloric disengaged in the process available for decomposing the molecular arrangement of the matter of the wood. Could this end be fully attained, it is evident that the whole of the carbonaceous matter might be obtained in the form of charcoal. How far this is from being accomplished in the meiler system, those engaged in the business are best aware; as likewise how great a loss the slightest variation of temperature inflicts upon them. This regulation of the heat is, however, a problem, the solution of which would involve the removal of serious difficulties—a fact which will be readily admitted when the amount of water to be discharged as steam, the volume of gases liberated, and of air passing through the pile, are considered.

A method adopted in Sweden, which seems to be an improvement on the common plan, is to conduct

the draught downwards instead of in the ordinary way; and if the pile were constructed upon a base sloped from the centre to the exterior, this would allow of the draining of the tar, acetic acid, water, *et cetera*, into a suitable vessel. Pipes might be disposed through it, so as to conduct the draught from the vertex to the base of the cone, and all converging into a tank, where the vapors would be condensed as far as possible, the remainder passing out through a flue into a chimney of sufficient height to generate a draught powerful enough to carry on the combustion. By this course all the heat would be utilized, and the moisture disengaged would be prevented from passing through the ignited wood—a circumstance which causes considerable reduction of the charcoal left.

Another species of charring is that in which the heat is exterior to the wood which is to be carbonized, and is produced in an adjoining fire. Of this description of carbonizers is that represented in Fig. 33, a construction of brickwork, having apertures suited to the convenience of the workmen for charging and withdrawing the products. Of these, *A* shows the orifice through which the wood is introduced till it rises as high as this opening, after which it is closed, and the remainder of the interior charged through the superior aperture, *B*, and the orifice for the passage of the products of distillation is through the pipe, *C*. The fire which serves

Fig. 33.

to bring the contents to the point of decomposition is made on the grate, *D*, and the air which is to maintain its combustion enters by the ashpit, and is regulated by a door, *E*. When the kiln is charged, the apertures, *A* and *B*, are blocked up with bricks, or closely fitting lids. As soon as the walls have acquired so much heat as will be necessary to complete the charring, the communication with the air is cut off by closing the door, *E*. In carbonizing in this manner, the charring is more regularly effected, although the supervision of the attendant cannot be so well exerted as when the ordinary meiler is resorted to; in the latter, however, the influence of the weather can scarcely be controlled, however watchful the workman may be—a condition effected by the walls of the kiln, and hence its superiority.

Differing from the kilns of this description, but still

less advantageous in point of execution, are those kinds of carbonizers which char the wood without allowing the products of the combustion to come into contact with the materials to be decomposed. They possess an advantage over others, inasmuch as all the volatile products are recovered in the condenser, without anything being lost from a combustion taking place in contact with them. This advantage is partly neutralized by the large amount of fuel which is required to bring their contents to the proper working temperature, and the necessarily small volume which must be operated upon, owing to the non-conducting qualities of wood and charcoal. No less than a quarter of the product in charcoal is consumed for this purpose, even when the combustible gases which pass through the condenser unarrested are economised in the grate.

The close distillatory apparatus or retorts are the most eligible for the decomposition of pine wood, and such as contain a large amount of resins; and though, at a distance from the site where the wood is felled, they are generally composed of iron, yet near the locality they are sometimes constructed of well-tempered clay. Those known as tar-retorts are composed of two hollow cylinders, one within the other, and differing six or eight inches in diameter. The inner of these receives the wood, and is a little longer than the outer one. The space between them is appropriated to the fire, which is maintained by a current of air rushing in through apertures in the outer walls. A funnel shape is given to the base of the retort, and this is made to terminate in a pipe which traverses the outer cylinder, and abuts in a tar cistern where the products of distillation collect. By means of an aperture at the top of the inner cylinder the wood is introduced, and after the charging is performed, and all the outlets closed with the exception of those at the base, the fire is lighted in the intervening space between the outer cylinder and the retort, and the heat continued as long as volatile matters pass over to the receiver. When these cease, or sooner, provided the walls are sufficiently hot to finish the distillation, the fire is extinguished, and the apparatus allowed to cool.

A very good form of retort for the distillation of wood and the production of tar and charcoal, is that shown in Fig. 34 annexed. The body, A, of the retort is of cast-iron, imbedded in masonry or brickwork, so that the flue from the grate courses spirally to the top, where it turns off to the chimney. In the upper part of this case is a movable cover, B, through which the wood is introduced, and by which the charcoal is removed when the charring is finished. An outlet is made at the top under the rim, to which a pipe, C, is fixed that communicates with a large condensing vessel, D, covered at the top; this is connected with another, E, wherein all the condensable matters which escape from the first are arrested

and conducted to a recipient by the pipe and stopcock, O, whilst the non-condensable gases are reconducted by a pipe, F F, over the grate of the furnace, G, to be burned,

Fig. 34

and thus economise the fuel. The fire is made of faggots and brushwood, and is maintained till gases and vapors are abundantly evolved, at which stage a stopcock in the pipe, F F, is opened, and the inflammable products of the distillation are allowed to flow in over the fire, where, in burning, they produce as much heat, with a little addition of fuel, as will char the remainder of the contents. After the condensable matters cease to flow over, this tap is shut, and the retort is left to cool for a period of sixteen to twenty hours.

Such are the principal methods resorted to for the manufacture of charcoal from wood for the requirements of the smelter, the powder-maker, and others. It is evident, from the nature of the several processes, that considerable difference must necessarily exist between the charcoals produced, as well in their intrinsic value as in their physical appearance. This partly depends on the species of wood employed; but all the difference is not to be attributed to this circumstance. The study of charcoal, with a view to its application in the works where it is chiefly consumed on the Continent, has led to a modification of the usual mode of charring, by which a larger volumetric yield has been insured, answering all the purposes required. This product is designated *torrefied wood*, or *red charcoal*, from its reddish-brown appearance. BERTHIER was the first to call attention to this variety; but lately SAUVAGE conducted some experiments, from which he deduces that the amount of combustible matter obtained by the charring of wood does not increase after exposing the material to a suitable heat during a stated period, but that, on the contrary, a loss is sustained in the quantity. He limits the proper period to five hours and a half. The results of his experiments are transcribed in the annexed table, which shows the loss sustained in weight, and the volume at the intervals mentioned:—

100 lbs. Wood charred for	3 hours.	4 hours	5 hours.	5½ hours.	6½ hours.	Mould Charcoal.
Weighed 100 cubic feet by similar treatment } measured	65·4 pounds. 86 C.F.	53 pounds. 76 C.F.	47 pounds. 58 C.F.	41·5 pounds. 55 C.F.	39·1 pounds. 52 C.F.	17·2 pounds. 33 C.F.

cent. of the wood taken, whilst the produce of the kilns in the same quarters has been shown to be only a mean of about twenty-six per cent.; and this, when the quantity consumed in the operation is deducted, leaves only about twenty-two per cent., or rather less than that afforded by the ordinary process. It must be remarked, however, that the meiler yield was in these cases an exception to their general produce, which is found much lower than the numbers so given, even when thick wood is operated upon; and the proportion is much further decreased when small wood is charred in them. It is a well-known fact, however, that none of the methods give, in the form of charcoal, more than two-fifths of the real amount of carbon in the dry wood. According to EBELMEN, this loss is occasioned not entirely by the products of the distillation carrying off portions of it in combination, but by the direct combustion of the charcoal in an incandescent state, caused incidentally by the oxygen of the air passing through it, and converting it into carbonic acid and carbonic oxide. This he proved by the comparative analysis of the vapors from the temporary chimneys in the meiler, and of those developed in close vessels, where contact of the fire was entirely excluded. Of course, if the portion of carbonic acid which must necessarily be generated is permitted to traverse the incandescent charcoal, it will suffer decomposition at that temperature, and as much more carbon as it contained will be assimilated and lost to the charcoal-maker, the whole passing off in the form of carbonic oxide. The charcoal-burner's efforts should be directed to prevent this, by conducting the air which enters the meiler over the uncarbonized wood; and after it passes that part of the heap where combustion is active, withdrawing it by means of the temporary openings in the cover, over the portion yet undecomposed, so as to be out of the reach of the made charcoal. It is almost impossible to effect this thoroughly, but the efforts made with that view by those engaged in the business show that its importance is appreciated, and doubtless a remedy will soon be found which will render the process more effectual than it is at present.

QUALITY OF THE CHARCOAL.—A few considerations may now be submitted with reference to the quality of the charcoal. Independently of the fact of the densest being the best, it happens that during the making it may be deteriorated, either by imperfect charring, or by pushing the process beyond the proper limits. In the former case the product is not good, on account of the gaseous elements which it retains, and which being disengaged in its subsequent application as fuel, render it less efficient for producing a high temperature; in the latter case it becomes so brittle as to be incapable of being handled without falling to powder: and the same crumbling occurs in the smelting furnace, where it is more injurious.

Good charcoal is very dark, possesses a bright lustre and somewhat conchoidal fracture; it resists gradual pressure to a considerable extent, and produces a sharp sonorous sound when allowed to fall upon a hard body. It should burn when ignited without either flame or smoke, and when handled no stain ought to remain. Although in bulk it floats in water,

owing to the arrangement of the particles, its specific gravity, when ground so as to destroy its porosity, is much higher than that of water. In addition to the carbon of which it chiefly consists, a certain amount of oxygen, hydrogen, and other gases is found in it, together with the mineral matter of the wood. The greater or less proportion of the former affects its calorific power, and renders it more or less eligible for certain uses in the arts.

The following analyses of two samples of charcoal prepared by the meiler system, show the quantity of the different ingredients remaining, even after the charring has been carried to its utmost limits:—

	Centesimally represented.	
	Charcoal from Young Oak.	Charcoal from the Aspen.
Carbon,.....	87.68	87.22
Hydrogen,.....	2.83	3.20
Oxygen,.....	6.43	8.72
Ash,.....	3.06	0.86
	100.00	100.00
Loss by distillation,.....	13.02	17.07

Red charcoal retains a somewhat larger quantity of the above gases, than the product of the meiler or the close retort. The following table embodies the results of M. VIOLETTE'S analyses of the charcoal prepared by the action of superheated steam, according to his process:—

Species of Charcoal.	Elementary Constitution Centesimally Represented.

In this table considerable difference in the yield of carbon is apparent; but as the samples were prepared by the application of the same temperature, it is evident that the inequality must be owing to a difference in the principles contained in them, and to the greater or less difficulty with which they are decomposed. It must be remembered, however, that the woods them-

selves do not contain the same amount of carbon. Were the water and ligneous matter the same in all, probably the approximation of the results of analysis would be closer. The quantity of inorganic salts in the various samples is very small, much less so than one might suppose, considering that wood containing about twenty per cent. of moisture gives from one-third to one per cent., all of which is retained in the charcoal produced from it, generally amounting to about twenty per cent. The following results obtained by WINKLER are, therefore, more in accordance with what might be expected:—

	Ash Centesimally.
Lime-wood charcoal,.....	3.55
Maple,.....	2.27
Ash,.....	2.27
Elm,.....	2.17
Willow,.....	1.50
Fir,.....	1.44
Pine,.....	1.38
Poplar,.....	1.30
Beech,.....	1.25
Scotch fir-wood,.....	1.11
Birch,.....	0.80
Oak,.....	0.75

Many varieties afford as much as five and even ten per cent. more, especially if the wood has been grown upon silicious soils.

A remarkable property of charcoal is, that it absorbs with avidity gases and vapors, condensing them within its pores to a most surprising extent, as shown in Vol. I., p. 764. In consequence of this property, it cannot be exposed to moist air for any length of time, without exerting a hygroscopic action, and assimilating a variable per centage of water, in proportion to the time of exposure and the humidity of the atmosphere. From experiments made with freshly prepared charcoal, NAU obtained the subjoined numbers after exposing the samples twenty-four hours to an atmosphere loaded with moisture:—

	Amount of water absorbed in twenty-four hours. Centesimally represented.
White beech charcoal,.....	0.80
Ash,.....	4.06
Oak,.....	4.28
Birch,.....	4.40
Larch,.....	4.50
Maple,.....	4.80
Pine,.....	5.14
Red beech charcoal,.....	5.30
Horse-chestnut,.....	6.06
Elm,.....	6.60
Alder,.....	7.93
Scotch fir,.....	8.20
Willow,.....	8.20
Italian poplar,.....	8.50
Fir,.....	8.90
Black poplar,.....	16.30

This proportion slowly increases when the exposure is prolonged, as proved by WERLISCH, who found that one hundred parts of charcoal, weighed on the 24th of June, became—

On the 30th of June,.....	104.35
„ 7th of July,.....	105.63
„ 16th „.....	106.57
„ 29th „.....	107.62
„ 20th of August,.....	108.16
„ 17th of September,.....	108.44

These numbers do not indicate, however, the actual

amount of contained moisture, as the charcoal had not been taken immediately from the meiler, so that it might have already absorbed from three to four parts of water, as the former table shows.

The lower the temperature at which the carbonization has been effected, the proportion of water is greater. The results of VIOLETTE's experiments on this subject are given below. The samples, consisting of charcoal from black alder, prepared at increasing temperatures, were exposed in a room, the air of which was saturated with moisture, and the amount of absorption determined every eight days, no numbers being taken till the results of two successive trials agreed —

Temperature of carbonization. Deg. Fahr.	Quantity of water absorbed by 100 of charcoal	Temperature of carbonization. Deg. Fahr.	Quantity of water absorbed by 100 of charcoal.
302	20.862	554	6.920
320	18.220	572	7.608
338	18.180	590	7.200
356	16.660	608	5.554
374	11.626	626	4.504
392	10.018	644	5.904
410	9.742	662	5.894
428	8.954	810	4.704
446	8.800	1873	4.676
464	6.666	2012	4.444
482	7.406	2232	4.760
500	6.836	2372	2.224
518	6.306	2732	2.204
536	7.879		

To account for the very high numbers with which the table commences, it is to be observed that the product resulting from the low degrees of temperature was not more than half-burned charcoal, hence its proportionally greater hygroscopic power.

The density of charcoal depends chiefly on that of the wood; hence it is evident that the relative weight of the wood will afford a good idea of the nature of the charcoal produced from it. This fact is of much importance, as the value of the material for fuel may, to a considerable extent, be deduced from its specific gravity. The value of this, for several species of wood, as determined by HASENFRATZ, is as follows:—

	Specific gravity.
Birch wood charcoal,.....	0.203
Ash,.....	0.200
Wild service wood,.....	0.196
Red beech,.....	0.187
White beech,.....	0.183
Elm,.....	0.180
Red fir,.....	0.176
Maple,.....	0.164
Oak,.....	0.155
Pear,.....	0.152
Alder,.....	0.134
Lime,.....	0.106

These numbers, however, merely indicate the weight of various samples when the interstices have been filled with air, and, therefore, do not represent the true gravity. In the appended table, the real specific gravity as determined by VIOLETTE is given. The course which the latter adopted was to immerse the sample, already weighed in air, in a flask three-quarters full of distilled water, allowing it to remain exposed to light for eight or ten days; by filling the flask at the end of this period to the usual mark, and then determining the total weight, and from this deducting that of the flask and liquid, the difference by the usual formula gave the specific gravity:—

DENSITY OF THE CHARCOAL OF BLACK ALDER PREPARED AT INCREASING TEMPERATURES.

Heat of carbonization. Deg. Fahr.	Density of charcoal.	Heat of carbonization. Deg. Fahr.	Density of charcoal.
302	1.507	626	1.428
338	1.490	662	1.500
374	1.470	810	1.709
410	1.457	1873	1.841
446	1.416	2282	1.862
482	1.413	2732	1.869
518	1.402	fusing point of	2.002
554	1.406	the retort, }	
590	1.422		

The density in this case is therefore greater than that of water, but still it varies to a certain extent with the temperature at which the substance has been prepared; thus the charcoal obtained between the temperatures 302° and 518° Fahr. decreases in density from 1.507 to 1.402; while, on the contrary, that which is afforded between 518° and 662° increases from 1.402 to 1.500; and from this point the density continues to increase, till, at the fusing point of the vessel, it becomes double that of water.

Before proceeding to the other materials which constitute fuel, a few observations may be made on the power of charcoal to conduct heat, and the facility with which it undergoes combustion.

It is a well-known fact that the product resulting from a high temperature, or in other words, black charcoal, is a much better conductor of caloric than that formed under the influence of a lower heat; it requires also a higher temperature to ignite it; but when this is effected, and an adequate supply of oxygen is kept up, the combustion proceeds steadily, and the heat given off is regular and sustained. Considerable difficulty is found in making accurate determinations of the conducting power of charcoal. The ingenious method of M. VIOLETTE deserves particular notice, as it affords in a simple manner the conducting power of this substance, and may, by a slight adaptation, be rendered available for determining questions of importance concerning the philosophy of heat in bodies.

Fig. 37 shows the arrangement of the apparatus, in which A represents a glass flask half filled with water and heated by a lamp; this is connected with another glass cylinder, B, closed by tightly fitting bungs, by means of a glass tube, *h*. In the superior cork or cap of the tube, B, is an opening which receives a third tube, D, nearly filled with mercury, in which is immersed the sample of charcoal, the conducting power of which is

to be determined. This is seen in the figure at E, and in its upper end there is made a perforation for the reception of a small mercurial thermometer, F, for the purpose of registering the rays of caloric conducted by it. The entire length of the sample, in the experiments made by the inventor of the apparatus, was 0.984 of an inch, of which 0.236 of an inch was immersed in the mercury; 0.195 of an inch of the sample intervened between the latter and the bulb of the thermometer. The source of the heat was the steam circulating in the vessel, B, and escaping through the outlet, c. A portion of the caloric of the vapor was abstracted by the mercury, so that it was retained at about 204.8° Fahr. The numbers given in the annexed table were obtained by noting the register of the thermometer at intervals of five minutes till the indication remained stationary: this happened after fifteen minutes' immersion. By employing a bar of iron of the same dimensions as that of the charcoal, and introducing the bulb of the thermometer in a like manner, a comparison was instituted between the charcoal and this substance of known power of conduction.

CONDUCTING POWER OF CHARCOAL OF THE SAME WOOD—BLACK ALDER—PREPARED AT INCREASING TEMPERATURES:—

Temperature. Of the carbonization.		Indication of the Thermometer.			Conducting power of Charcoal compared with that of iron represented by 100.
		After 5 minutes.	After 10 minutes.	After 15 minutes.	
316° Fahr.	27.00	56.00	57.0	57.5	59.5
392 "	27.00	57.00	57.5	58.0	60.1
482 "	27.00	57.50	57.5	58.0	60.1
572 "	27.00	58.00	59.0	59.5	61.6
1873 "	26.50	61.00	62.0	62.0	64.2
2282 "	26.50	62.00	62.50	63.0	65.2
2732 "	26.00	63.00	63.5	64.0	66.3
Charcoal of gas retorts.	26.00	81.00	82.0	82.0	84.7
	22.00	96.50	96.5	96.5	100.0

The numbers in the last column were obtained by multiplying those of the preceding one by 1.036. Between the temperatures 572° and 752° the conducting power is low, and is nearly the same in the wood and the charcoal produced from it; but when the heat is elevated, the density of the charcoal increases rapidly, till it is about two-thirds that of iron.

Regarding the combustion of charcoal, it will be observed, upon taking pieces of it, produced by different modes of working or by unequal degrees of heat—plunging one end of each in the flame of alcohol till ignited, and then allowing it to rest in tranquil air—that very different phenomena will be exhibited in the combustion. The charcoal made at low temperatures, say between 302° and 482° Fahr., burns with a long yellow flame, disengaging large volumes of smoke, and retaining the temperature of combustion for about fifteen minutes, at the end of which time the cylinder will have burned about half an inch. On the other hand, if the wood has been submitted during carbonization to a heat between 482° and 809°, the combustion of the charcoal under the same circumstances is characterized by a clearer flame, which is less fuliginous and persistent, and by being continued for a longer time, more especially with those samples prepared between 482° and 662°. The charcoal pre-

pared at 809° does not burn so well as any of the samples obtained at a lower heat, nor does the ignition continue so long. When the carbonization is effected at the higher degrees represented in the foregoing table, the cylinder of charcoal, on being introduced into the flame, becomes red-hot like a bar of metal, affording no flame, and is extinguished immediately on withdrawing it, without giving any indication of combustion or leaving a coating of ash. In this last case, the fingers are unable to hold the cylinder whilst its end is in the flame for any length of time, in consequence of the freedom with which it conducts the heat.

All the preceding samples, when reduced to powder, present the same phenomena with respect to combustion as when in solid pieces, only with greater intensity, because, on account of the air interposed, the ignition is easily propagated and maintained. When, however, the experiment is conducted in a very tranquil atmosphere, the burning ceases after a part is consumed. This effect must doubtless be owing to the carbonic acid, which, being heavier than common air, does not ascend with sufficient freedom to permit the oxygen of the latter to come in contact with the burning matter.

In many manufactories where this article is required in powder, great care must be exercised, as it often happens that spontaneous combustion takes place. The most inflammable charcoals take fire at 572°, and those that are prepared at the latter heat invariably ignite at a temperature varying from 680° to 716°, according to the nature of the wood. Charcoal, from light and porous woods, always burns more freely than that obtained from the hard and dense kinds; but even the same wood furnishes charcoal that ignites with greater or less facility according to the temperature at which it has been prepared, as may be seen from the following table:—

TABLE SHOWING THE TEMPERATURE AT WHICH THE CHARCOAL, FROM THE SAME WOOD, PREPARED AT INCREASING TEMPERATURES, BURNS.

Other particulars concerning charcoal, so far as relates to the manufacture of gunpowder, will be introduced under that head.

PEAT.—Another article of fuel, much employed for domestic purposes, as well as for many manufactures, in which it has lately found admittance, is *Peat*. Such is the name by which the brownish-black spongy substance, found in almost every country, filling up cavities, and constituting what is termed *bog*, is known. It is a product of vegetal origin, but differing from wood as well in the nature of the growth, as from the change which it has undergone atomically through the combined agency of time and pressure. It was once supposed that this formation was, in point of time, coeval

with the disposition of the face of the country into hills and valleys; by some it was considered a bituminous deposit from the sea—the wreck of floating islands previous to the great convulsions which the earth underwent during the formation of the present continents and islands. By others it was even regarded as an organic substance in a state of vitality, and actually growing; but all these notions are now abandoned, and a more rational and philosophical view of its nature and production has been arrived at. From examining its structure, it has been found that it is constituted of vegetal matters, generally mosses and species of aquatic plants in different stages of decomposition; and from this circumstance, as well as from the general appearance of the localities where peat abounds, its formation is now accounted for in the following manner:—

At the present day it may be observed, that where pools collect, the soil under which is retentive, the water not being absorbed, stagnates, and, provided the surface evaporation is not great, forms a pond. Round the borders of this, various kinds of aquatic plants, sedges, rushes, *et cetera*, soon make their appearance, and by reproduction, gradually creep in towards the centre till the whole surface becomes covered. In course of time, when several races of these have succeeded one another, and mud and slime have accumulated at the roots and round the decaying stems, a spongy mass results, which is well calculated for the propagation of moss. Under a constant supply of moisture, these various species continue to luxuriate, and, by progressive growth and *eremacausis*, ultimately give rise to a composition in every respect similar to that constituting the various peat-bogs. That some such natural process has been the cause of the production of peat appears from its composition and the localities in which it is found. These are chiefly in the temperate zones, where evaporation is slow, and the atmosphere is generally more or less saturated with humidity. It may be conceived that in the origin of these formations, the retention of the water, whether from rain or springs, in extensive basins, led at first to the development of vegetal growth in the manner above indicated, and that the necessary moisture being supplied in abundance, the accumulation became so rapid, that ultimately the surface assumed the appearance of land; and, as decomposition proceeded, a degree of solidity was given to the mass to support denser bodies, such as shrubby plants. It would appear that this organic growth was rarely restricted to the original basin; but that, as it accumulated, it spread over adjacent land, which, in time, became a morass. Evidence conclusive enough of this exists in the fact, that whole forests, of almost every description, such as oaks, firs, ash, birch, yew, willow, *et cetera*, have been overwhelmed under its gradual but steady advancement, and are found in all positions at the bottom of peat-bogs. Generally, this formation is met with in climates of a moist nature, in level countries, where imperfect natural drainage exists, although it is found in considerable beds in upland districts. The very extensive peat moors on the coasts of the German Ocean, especially in Holland and Northern Germany, and in many tracts in Ireland and Scotland, are examples of the

former; whilst the deposits encountered high up the Alps, in the Vosges, and in the Jura, illustrate the latter. In mountainous districts, in addition to the imperviousness of the rock to the moisture, the constant formation of clouds upon those elevated regions favors the growth of the mosses and plants, the decomposition of which contributes to the production of quagmires.

DARWIN states that, in the Southern hemisphere, peat does not occur nearer to the equator than the latitude of 45° ; that the composition there met with results from the decomposition of the plants and grasses. The circumstance that no mosses, so far as can be ascertained by strict examination, enter into the species of peat found in South America, favors this view.

The extent and depth of the peat-bogs vary considerably in the different countries where they are found, and depend on circumstances quite distinct from each other. It is evident that the area which they may occupy is intimately connected with the distribution of the water, from whatever causes. In Holland and North Germany, the water of the ocean seems to have largely contributed to the moisture in which they originated. The peat-moors of the Grand-duchy of Hesse would appear to be occasioned by the overflow of the Rhine, whereby these tracts were irrigated, and the waters remaining, and necessarily becoming stagnant, the place was soon changed, and, instead of remaining a swampy district, it ultimately became a morass. On the other hand, the thickness of the beds of peat, seems, from repeated observation, to be dependent upon the nature of the subsoil. Where the bottom is quartzose, the deposit is invariably not very thick; but if it be such as yields by disintegration a clayey coating, the depth and extent are much more considerable. The morasses of Holland are to a considerable extent about six feet in depth, as are likewise those in upland situations; whilst many of the peat bogs in Ireland are from thirty to forty feet in depth. On intersecting these, it appears from the fact of layers of gravel, clay, shells, *et cetera*, being interposed horizontally, that these tracts have been swept over with violent currents of water; such layers, however, are never more than a few feet in thickness, and, seem to have retained all the conditions favorable for the growth of the plants conducive to the formation of peat.

From its physical constitution, this substance may be regarded as a kind of fossil fuel, and, undoubtedly, it is one of the most extensive sources known. Viewing it as the product of the decomposition of plants carried on through a long succession of ages up to the present, it is natural to expect that when cut vertically, differences should appear showing the advancing state of decomposition. In every instance, almost, this progressive change is exhibited, and, consequently, peat is classed into—

Recent Peat and Older Peat, from the appearance it presents. The former bears distinctive traces of its origin in the roots, leaves, and stems of plants, the structure of which is still retained. It is very porous, tough, and elastic in some tracts; but in others, especially where the bog is well drained, very brittle. The color varies, with the age and the progress of the de-

composition, from a light to a blackish-brown. In the second, to which the preceding gradually inclines, no traces of fibrous matters—such as roots, stems, or leaves—are observed, but it presents when cut a pitchy shining hue—is dense and fine in the grain. Preference has always been acceded to this as a fuel from its superior gravity, and the greater heat which it produces when undergoing combustion. From the change which the vegetals pass through, it is evident that the usual process of putrefaction is carried on in the ordinary way at the commencement; but as the surface grows, and contact with the air is cut off, the mass is left to the play of the affinity of its elements, rendered more active by the pressure which it has to sustain. The alteration is attended with the evolution of marsh gas—bihydride of carbon $C H_2$ —and carbonic acid, in the same way as in every case of partial destructive distillation; but from the excess of moisture present, it is evident that this action cannot, in the case of peat, be so complete as in coal, which is analogous in nature. Many bodies are detected in peat, however, which are not contained in coal, although the ultimate elements of both are the same. SPRENGEL detected in peat considerable quantities of ulmic acid—known also by the names *ulmin*, *humus*, *gein*, and *geic acid*—the composition of which, as obtained from turf, is expressed by the formula $C_{40} H_{15} O_{12} N$; and when procured from mould, by $C_{40} H_{15} O_{14} N$. This principle is dissolved out by alkalies, and precipitated from their solutions by acids in brownish flakes; this, however, as also the other varieties of resins examined by MULDER, are of little use hitherto in the arts.

The density of peat varies with the relative position in which it is found, with the thickness of the stratum, and the amount of mineral matters which it contains. Freshly cut, it is saturated with water to the extent of eighty to ninety per cent. in some cases, and, when subjected to the ordinary process of air-drying, it retains a large quantity of this, amounting sometimes to thirty per cent.

The estimation of the gravity in this state would lead only to relative approximations, even if the percentage of moisture was known, and the species examined had undergone about the same degree of decomposition. As already intimated, however, the latter principally determines the difference of specific weight in peat from the same cutting. KARMARSH arrived at the following results with regard to Hanoverian peat:—

Species.	Specific gravity.
1. Light-colored young grass peat, nearly unchanged moss,.....	} 0.113 to 0.263
2. Young brownish-black peat—an earthy matrix intersected with roots,.....	
3. Old earthy peat without any fibrous texture,.....	} 0.240 to 0.600
4. Old or pitch peat,.....	
	0.564 to 0.902
	0.639 to 1.039

Of twenty-seven samples of peat examined by Sir ROBERT KANE and Dr. W. K. SULLIVAN, the results, as stated in their report in 1851, show that the maximum density was 1.058, and the minimum 0.235, a great many being under 0.600, as may be seen from the following tabulation of their gravities, coupled with the constituents of the ash, to which reference will be made further on:—

The carbonic acid found in the above analyses is, in nearly every instance, much less than what is required to saturate the lime, supposing the whole of the sulphuric acid to exist as sulphate of lime; this is accounted for by the high temperature necessary to incinerate the peat, having driven off the greater part of the carbonic acid.

- I.—Light, spongy, surface-peat, of a reddish-brown color, and composed almost entirely of *Sphagnum*, species of which are still distinguishable; from near Monastrevin.
- II.—Light surface-peat, of a reddish-brown color, containing small roots of *Erica*, also leaves of grasses and *Carex*; from Mount Lucas Bog, near Phillipstown, King's County.
- III.—Rather dense peat, of a dark reddish-brown color, in which the structure of moss is still observable; from the same locality as No. II.
- IV.—Light reddish-brown fibrous moss-peat, in which the *Sphagnum* is almost unaltered, as well as leaves of *Carex* and other plants, and the roots of species of *Erica*; from Twicknevin, Kildare.
- V.—Upper layer of fibrous red bog, composed entirely of *Sphagnum*, *Hypnum*, and other mosses; from Derrymullen Station of the Irish Amelioration Society.
- VI.—Dense peat, of a black-brown color, in which vegetal structure is nearly obliterated, but in which the leaves of grasses and *Carex*, with twigs of hazel and birch, are sometimes found; from Wood of Allen, Great Timahoe Bog.

- VII.—Light surface-peat, of a pale yellowish-brown; from Wood of Allen. The mass is very open-grained and fibrous in this sample, and *Sphagnum* and *Hypnum* are readily distinguishable.
- VIII.—Middle layer of the same bog, of a deep-reddish color. The mass is tolerably compact, but fibrous, having the structure of the mass very indistinct. A very few roots of *Erica*, and small twigs of birch and alder, and fir scales are found in it.
- IX.—Lower layer of the same bog, and from the same locality. This variety is compact and dense, of a deep blackish-brown color, with an earthy almost conchoidal fracture, and exhibiting a resinous lustre when rubbed. Vegetal structure nearly obliterated.
- X.—Good compact peat, of a blackish-brown color, and consisting principally of moss, with a number of *Erica* and grass roots and *Carex*. This sample is from Riversdale Bog, near Kimegad, and is used as fuel in Dublin.
- XI.—An extremely hard and compact peat, having the vegetal structure entirely obliterated, and exhibiting when broken a resinous conchoidal fracture. Scales of fir-trees and twigs of birch and alder, *et cetera*, occur in it; it is a valuable fuel. Locality—Riversdale Bog, near Kimegad.
- XII.—Very dense, dark, reddish-brown peat, from Anadruce and Cloncreim, on the Royal Canal. In this peat the vegetal structure is only occasionally perceptible.
- XIII.—Rather dense peat, of a dark reddish-brown color and compact structure, from bogs of Rathconnell, Wood Down, and Great Down, near Mullingar. *Sphagnum* indistinct, but leaves of the flag and stems and roots of *Erica* occur in a very perfect state in it.
- XIV.—Upper layer of a fibrous bog in the neighborhood of Banagher. It is a spongy mass, of a yellowish-red color, composed of almost unaltered *Sphagnum*, with occasional roots of *Carex*, *Erica*, *et cetera*.
- XV.—Rather compact peat, of a reddish-brown color, from the same locality as the preceding sample. In this kind, vegetal structure is very perceptible, although undistinguishable; the roots of the *Erica* are abundant, but the greater part is evidently derived from moss.
- XVI.—A more compact peat than No. XV., from the same bogs, consisting of fibrous or red bog, of a light reddish-brown color. Like the foregoing, the species is indiscernible in this, although organic structure is visible. Roots and leaves of *Carex* are exceedingly abundant in it.
- XVII.—Light surface-peat, of a pale reddish-brown color, from the bogs of Clonfert and Kilmore, at the mouth of the Suck, near Banagher. The mass is spongy, and is composed of almost unaltered *Sphagnum*, with a few stems and roots of *Erica*.
- XVIII.—Peat from the same locality. It is rather compact but fibrous, and of a light reddish-brown color passing into black.
- XIX.—An exceedingly dense peat, of a conchoidal earthy fracture, from Athlone bog. In this the vegetal structure is almost completely destroyed; but when apparent, indicates remains of *Carex*, grasses, and *Erica* in abundance.
- XX.—A rather dense peat, of a blackish-brown color, in which the structure of moss is no longer visible, but abounding in remains of *Carex*, grasses, and roots and stems of *Erica*; from the Curragh or Clonbourne bogs near Shannon Bridge.
- XXI.—A dense peat, of a dark reddish-brown color, from bogs along the Shannon. Remains of *Carex* and grasses are abundant in this variety, but *Sphagnum* is very indistinct. It is used in steamers plying on the river.
- XXII.—A light fibrous peat, of a reddish-brown color, formed evidently of a great number of plants, and in which the structure of moss is very distinct. Species of *Sphagnum* and *Hypnum* are observed, and also remains of *Carex* and grasses, the roots of *Erica*, the bark of birch, and probably alder-twigs in abundance. It is from the same locality as No. XXI.
- XXIII.—A very dense peat, of a blackish-brown color, of a compact though very indistinct structure. The remains of *Carex* are abundant, as also roots of *Erica*. It forms an excellent fuel. Locality the same as No. XXI.
- XXIV.—A very dense blackish-brown compact peat, from the same locality as No. XXI. In this species, vegetal structure is almost obliterated. It has an earthy fracture, and is full of the tubes of the bark of hazel, birch, and alder; occasionally scales of pine bark and leaves of *Carex* and grass are met in it.
- XXV.—A rather dense reddish-brown peat. The structure of this is indistinct, but altered *Carex* leaves and fragments of twigs and roots are observed in it. Locality the same as No. XXII.
- XXVI.—Rather compact and moderately dense peat, of a dark reddish-brown color. Structure of moss almost obliterated. Fracture earthy. Abundance of leaves, stalks, and roots of grasses, *Carex*, *et cetera*. Same locality as No. XXII.
- XXVII.—A dense jet-black peat. Structure of moss completely destroyed. Fracture earthy, tending to conchoidal; assuming resinous lustre when rubbed. Abundance of remains of *Carex* leaves, and a very few fragments of bark, apparently of hazel. Same locality as No. XXII.

From the results of the ultimate analysis of dried peat, it is observed that the numbers which are found do not correspond with the analysis of dried wood. The following analyses by REGNAULT and MULDER show the centesimal contents of carbon, hydrogen, and oxygen:—

Locality.	Carbon.	Hydrogen.	Oxygen.
Vulcaire,.....	{ 59·57 5·96 34·47 Regnault.		
	{ 60·40 5·86 33·64 Mulder.		
	{ 60·06 6·21 33·73 Regnault.		
Long,.....	{ 60·89 6·21 32·90 Mulder.		
	{ 60·21 6·45 33·34 Regnault.		
Champ de Feu,...	{ 61·05 6·45 32·50 Mulder.		
Friesland,.....	59·42 5·87 34·71 "		
Friesland,.....	60·41 5·87 34·02 "		
Holland,.....	59·27 5·41 35·35 "		

In these samples, the numbers are calculated after deducting the ash. It is a well-ascertained fact that a greater or less quantity of nitrogen is invariably contained in peat, but this element appears to have been overlooked in the preceding. To show the average extent of the contents of nitrogen, the following analyses, selected from the *Dublin Journal of Industrial Progress*, so ably edited by Professor SULLIVAN, are submitted. The materials were taken from the same localities as mentioned in the foregoing table; but before subjecting them to analysis, they were thoroughly exsiccated at a temperature of 220° Fahrenheit:—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen, mean.

Kane and Sullivan.

intimately associated with heat, although the value of the charcoal which the substance affords as a calorific agent has been attested by practical skill and theoretical calculations. Attempts have long been made in Holland and some states of Germany, to render peat more profitable, as well in manufacturing operations as for domestic purposes; but it is remarkable that in a country such as Ireland, where, compared with other nations, the cost of labor is low, with one exception nothing has been done to convert her area of *two millions eight hundred and thirty thousand acres* of the finest bogs in the world to her advantage, although, if properly treated, they might prove a source of immense wealth. This neglect of the national interests seems still more inexplicable, when it is considered that the wealth requisite for successful manufacturing enterprise is already in the hands of the people, but lies a mere waste, useless to the possessor and to the universal interests of the community. It would appear, however, that something like an incipient spirit of enterprise is growing in the Irish mind, and, if this be fostered by the hand of science, doubtless, ere long, many of the hidden treasures which lie at the feet of the impoverished population, will be developed to the advantage of the parties immediately concerned, and the prosperity of the nation at large.

For domestic purposes, the peat is prepared by a very simple course of operations, differing sometimes according to its nature and thickness.

In every case the surface layer, which contains the living plants and their roots in the natural state, is stripped off to the depth of six to nine or twelve inches. The material is then cut with a kind of spade known as the *slane*, which has a wing bent at right angles to the blade of the instrument, so as to form with the latter two sides of a square. Sometimes two such wings or ears are added to the tool, and at the outer end these are united by a plate of iron which gives to it the appearance of a hollow rectangular cube, open at both ends. By this instrument the peat is cut in long square masses, and then spread upon the sward, where it spontaneously loses its water. After the bricks have acquired sufficient consistency, they are piled up on end so as to afford a more thorough exposure to the air; and finally, when desiccation has advanced, the turf, as it is then called, is piled together, being built round by a kind of clamp construction of the sods or bricks, and left till the material becomes as dry as it can be made by exposure to the air. Such is the mode adopted when the peat is sufficiently elastic to bear being so handled without breaking; when, however, the material is brittle and will not admit of being used in this way, it is dug out with ordinary spades, shovels, *et cetera*, and all roots, stones, and such like solid bodies picked out. It is then spread in a layer of from twelve to eighteen inches in thickness, watered, and brought to a homogeneous mixture, either by the tramping of men or beasts, where the latter can be employed. Afterwards the surface is smoothed and moulded in forms, either with the hand or a small mould which indents the surface. When the excess of water has drained off and the peat becomes consistent, the bricks are cut

out with a long knife, and dried in the manner already indicated. In many moors or fens the peat is so surcharged with water that it cannot be extracted even with the spade; in this case the workmen employ a kind of dredge, by which the material is collected. It is deposited on a sloping sward, and after the superabundance of water has drained off and the mass becomes more consistent, it is moulded into bricks. The latter processes are usually resorted to in France, Germany, and most other localities where peat abounds. In Holland a different course is pursued, which, though more circuitous, is notwithstanding more effectual in producing a denser fuel than can be obtained by the foregoing methods. The upper stratum, which is light and fibrous in its nature, is nearly always moulded with the *slane*, though sometimes it is subjected to the same operations as the under layer. Generally, this is scooped out with a kind of ladle when it is not too wet, and carried to the tempering ground; where, by sprinkling with water, tramping with the feet, and tempering with a rake, it is brought to a homogeneous consistence, and freed from stones, bits of wood, leaves, and the like. In case the matter is slimy, and so thin that it will not admit of adhering together in masses, another kind of tool is employed, enabling much more peat to be abstracted, with less water, than if the ordinary iron ladle dredge were used. It consists of a ring of iron, the edge of which is sharp, attached to a long handle; the side of this band is perforated for the purpose of affixing the body, which is a thick cloth, and the whole forms an instrument not unlike a fisherman's landing-net. Much more peat is taken up by this, and the excess of water filtering through the meshes of the tool, the peat is in a state which will admit of being immediately worked. This very slimy material is kneaded in a kind of trough or tub, till it becomes thoroughly blended together. In this state it appears like a kind of mortar. The next operation is to prepare the sward on which it is to be spread. This is done by laying upon it a covering of hay, which is trodden down to a level, whereon the peat is spread to the depth of a foot or more. The depth is regulated by means of planks or boards set in parallel lines, and placed, as circumstances may admit, from twelve to thirty feet apart. It is usual to beat down the surface of these beds to give the peat a uniform thickness. After a few days, when the excess of water has, partly by draining off, partly by infiltrating into the soil, and partly by evaporating, disappeared, and the layer of matter has acquired a certain consistence, it is rendered more compact by treading. This part of the work is performed by women and children, who attach flat boards, about six inches broad and twelve to fourteen long, to their feet. Before this treading is finished, the peat has acquired such solidity that it will bear a person's weight upon it without sinking. The surface is again brought to a level by beating it with oars, shovels, and the like; and after this is accomplished, the surface is divided into squares, the sides of which are about four to five inches. When the tracings thus made are cut, the bricks are about eight inches long by four to five inches square in the section. The drying is performed

by placing alternate rows crosswise upon one another, reversing this order in a few days, and continuing the exposure till the most of the moisture has disappeared. When this is the case, the turf is stored for use, but it is necessary that the moisture be sufficiently expelled before this part of the business is performed, as according to DUMAS, when this is not effected, the stacks are liable to a fermentative process which raises the temperature so high as often to cause spontaneous combustion. It has been already stated, that one essential quality of peat, in relation to its value as a fuel, is its density and freedom from large quantities of mineral matters; but another is also required, namely, that it contains as little water as possible. However well exposed or prepared, air-dried peat always retains from twenty to thirty per cent. of moisture, and this expends a considerable quantity of the heat of combustion in its evaporation. When intended for particular purposes, such as for charring in heaps, for lime-burning, and such like purposes where it is to be piled up in large masses, or has to resist much pressure, the value of the material is enhanced by the quality of strength or solidity, because, if it were very brittle, it would prove almost valueless for either of these uses.

COMPRESSION OF PEAT.—The relative heating power of dense peat well dried is about the same as wood, and half that of coal; the lighter kinds prove to be not more than one-third as effectual as coal for heating. Prepared according to the improved processes which have lately been introduced, it gains considerably in calorific power, as much more combustible material is contained in compressed peat, bulk for bulk, than in the ordinary sods or moulded turf. Much difficulty, however, stands in the way of effecting this condensation of the article, owing to the elastic nature of the fibre, which causes a distention after the force is removed. The system of pressing each sod or mould, as in the preparation of artificial fuels, would never answer with peat, as the labour would be too great in proportion to the value of the material; and, besides, the supply which could be so furnished would be inadequate to the demands of a large consumption. This led Mr. WILLIAMS, a gentleman who has contributed much to the development of the industrial uses of peat in Ireland, to the adoption of powerful hydraulic presses, which, while they are able to overcome the elasticity of the material, can supply it in considerable abundance. It is questionable, however, if his endeavors have been remunerative, as it is difficult to eradicate the preconceived prejudice of manufacturers and traders against this species of fuel. The manner of compressing, as conducted in the Cappoge works, was to break up the fibre of the peat as much as possible after cutting, and then to place it interlaid with coarse cloths or coco-matting under the machine. After the action had been exerted during the period allowed, the material was found to be reduced to one-third its original volume, and to have lost about two-fifths of its weight. In this state, the peat, when thoroughly dried, is not so hygroscopic as when the drying is conducted in the open air and no pressure exerted, and the lighter kinds yield by compression a substance denser than wood; the lower stratum affords a product

still more so. The elimination of the water by pressure improves the quality of the peat in other respects, not the least of which is the reduction of the relative amount of mineral matters contained in it, for considerable quantities are carried off in the water that would remain if it were exposed to spontaneous exsiccation. It would appear that the increased expense of this process is immaterial, when the relative volumes of product it affords, compared with ordinary peat, and the large percentage of water which the latter contains, are considered; for, whereas the latter costs three shillings and sixpence per ton at the bog, the prepared article can be had at five or six shillings. Mr. COBBOLD's method is to convert the peat into a magma, with the addition of water if necessary, and when by means of *centrifugal* power this is subsequently got rid of, a very dense product is obtained. The course recommended by Mr. STONE as described in his patent, sealed in March 1850, is the use of a box divided into a number of compartments suited to the size of the machine, and pressure to be exerted upon this, by rollers adapted to one another by means of leverages. Figs. 38 and 39 are vertical and side views of this arrangement, where the same letters indicate similar parts in each figure. A and B are cast-iron rollers, the latter of which is fixed in a stationary bearing, C. D is an adjusting screw, by means of which the roller may be raised or lowered at

Fig. 33.

Fig. 39.

pleasure; this screw works in the lever, F, the fulcrum of which is at the top of the side frame, and the handle connected with the long one, H, by the rods, I, I, which are adjusted by the screw, K. Pressure is exerted upon the lever, H, by sliding the weight, J. The friction rollers are shown at L L L L, for supporting the pressure box, M, before or after it has passed the pressure rollers, A B. Upon the shaft of the latter, two toothed wheels, P P, are fixed, which are worked by two pinions, N N, upon the shaft, O; the wheels, P P, gear into two toothed racks at each side of the pressure box, and serve to carry it along under the pressure rollers already indicated.

The box is such that it contains another one, R, in

which the peat is condensed; this is divided into sixteen compartments by means of bevel-edged knives, *a a*, fixed transversely in the cover, and *b b* in the bottom, and so corresponding with one another that when pressure is exerted they are nearly in contact. The longitudinal knife in the middle separates the interior into two divisions.

Motion is given to the whole by means of a winch-handle and fly-wheel appended to the ends of the shaft, *o*; when the motive is steam, the handle is substituted by a drum on which a strap works. The lever, *h*, may be lifted by means of another lever shown in the figure, so as to remove all pressure. The method of operating with this machine is to fill the movable box with peat, after which it is placed inside the box, *m*; the lever, *h*, is raised, and the box is drawn forward by putting the shaft, *o*, in motion. When it has come under the roller, *h* is let down so as to bring *A* in contact with the lid of the box. From the time that the verge of the box has entered under the roller till it has passed the centre, the lid is in an inclined position, varying from an angle of 10° or 15° . At the time the roller is at the centre, the cover will have assumed a horizontal position, and a uniform pressure will be enforced upon the entire contents. When the box has passed through the roller, the lid is taken off, and the compressed material removed and exposed to thorough desiccation. The compartment is again filled, the cover fitted on, and, by reversing the motion of the handle, the box is made to pass the same way backwards. Thus the compressed material is discharged at each end of the machine.

These and a few others are the means hitherto proposed for improving the quality of peat fuel, so as to remove its characteristic fault, namely, want of density; but it seems that as yet the processes have not been conducted with sufficient spirit, or the outlay in machinery is too great in proportion to the value of the material operated upon. It appears that in Ireland the chief improvement in this process must, for some time to come, turn upon the system of drying under sheds, so as to protect the peat from the influence of the rain, a considerable quantity of which it is capable of absorbing, and yet will appear dry to the touch. The amount of water thus retained considerably diminishes the heating power of the turf. This will be seen more clearly from the following data:—When a pound of pure dry peat is burned, and the entire amount of caloric which it yields is conducted through water, it will be found that six times its weight of this liquid will be raised to 212° . In ordinary turf the fourth part of the weight is water, so that there is only three-fourths available as a heating medium. Were a pound of this consumed in the same manner as the foregoing, it is evident the caloric developed would raise only four pounds and a half to the boiling point. This quantity would, of course, evaporate the water contained in the peat, so that the visible effect would be as four and a quarter to six, or about thirty per cent. in favor of the dried material. Such a wide difference, it is needless to say, is sufficient cause for condemning the moist material even for domestic use, but especially in manufactories, where it is an object of

VOL. II.

the first importance that the fuel should exert the greatest possible effect in proportion to its bulk and value.

Before passing to the discussion of the action of heat upon peat, it will be well to devote a little attention to the consideration of the nature of those substances contained in it, as well as those which are artificially produced from it. It has been stated already—page 51—that by the action of alkalies upon peat, the greater part is dissolved, and that, when the liquor is further treated with acids, the *ulmin* is precipitated in flakes. This substance, which is the principal and most important component of peat in its ordinary state, is so analogous to woody fibre in its composition, that the changes which the material producing it has undergone, may be considered as sufficient to account for the difference. By the researches of BRACONNOT and others, it has been proved that in the fresh peat *ulmin* is combined with lime, and forms therewith a true chemical compound—ulminate of lime. Ulmin or humus, popularly termed vegetal mould, has the following composition when prepared from wood and sugar:

	From Wood.	From Sugar.
Carbon,.....	72.7	65.65
Hydrogen,.....	6.1	4.28
Oxygen,.....	21.2	30.07
	100.0	100.00

When peat is subjected to destructive distillation ammonia is invariably one of the products, a circumstance for which it is difficult to account, seeing that ulmin is entirely devoid of nitrogen, unless it be admitted that, during the progressive decomposition of that body, nitrogen is assimilated from the air, just in the same manner as decaying wood or vegetal matter takes up the same element. In the course of the decomposition of vegetal bodies, oxygen and nitrogen are absorbed and combined with the other elements, and the consequence is the formation of a new substance called by HERMANN *nitrolin*—a body that approximates closely in its composition to animal flesh. Such a metamorphosis may be explained by supposing that two equivalents of woody fibre take five equivalents of nitrogen and ten of oxygen from the atmosphere, and give off sixteen equivalents of carbonic acid; thus—

By a further change these elements are disturbed, and carbonic acid is produced together with ammonia. Besides these, several other new substances of a brown or black color remain, among which are ulmic acid, *et cetera*. DUMAS supposes that the ammonia results from the decomposition of animal remains embedded in the marshes; but the Editor is of opinion that it is mostly derived from the atmosphere.

When peat is exposed to the action of heat in close vessels, it affords a variety of substances, the principal being pyroligneous acid; a brown empyreumatic crystallizable oil, from which numerous products may be

H

extracted, and among them paraffin; carbonic oxide and carbonic acid, hydrocarbon gases, together with a variable quantity of ammonia. Industrial progress has invested several of these with a new value during the last few years, so much so that they have become special objects of manufacture. This has been shown under the heads ACETIC ACID, AMMONIA, ASPHALT, CANDLES, *et cetera*; and with regard to certain inflammable gases and other bodies, their importance will appear further on. The products of the distillation of peat are all useful in the arts, and consequently are in constant request. To provide them in sufficient quantity, or at least in some degree to supply the wants of the trades using them, a manufactory was erected a few years ago near the town of Athy, in Kildare, Ireland, for the purpose of distilling peat, and obtaining the useful products which it affords. This manufactory has now established itself, although it had many difficulties to contend against. It is worked on the principle of Mr. REES REECE's patent, sealed in 1849. The idea was derived from the application of inflammable gases to heating purposes by the late M. EBELMEN, for the utilization of inferior coals and other combustibles, by converting them into gases, the object being the production of those organic bodies already alluded to. These are produced in greater abundance from peat than from other combustibles, owing to the large amount of water in it, which keeps the temperature low during the distillation, and thus favors the formation of such products. The principle of the distillation is the introduction of a blast of air at the bottom of a furnace filled with the combustible. The heat developed in this part passing up with the gases through the mass, causes the destructive distillation of the latter, and the expulsion of the empyreumatic products with the combustible and other gases from the fire. By proper contrivances these are operated upon, in such a way that all the condensable substances are removed, and the inflammable products which cannot be liquefied are employed to heat boilers, stills, or evaporating pans required in the purification of the crude products. It is this application of all the products to economical purposes which renders the manufactory so novel in its nature, for the very substance operated upon is made to supply all the requisites for carrying out the manufacture, besides supplying the useful products.

For the following important details with reference to this manufactory, the Editor is indebted to the *Journal of Industrial Progress*, by Professor SULLIVAN:—

From repeated examinations of peat with reference to the amount of tar, oils, paraffin, and ammoniacal

salts which it yields, as well as from the researches of the patentee, most flattering results were anticipated from the development of this branch of industry. To carry it out, a company was organized, called the IRISH PEAT COMPANY, which stated in its prospectus that, by a manufactory capable of operating on one hundred tons daily, or thirty-six thousand five hundred tons annually, the following commercial results would be attained; namely,—

EXPENDITURE.

36,500 tons peat, at 2s. per ton,	£3,650
455 tons of sulphuric acid, at £7 per ton,	3,185
Wear and tear of apparatus, <i>et cetera</i> ,	700
Wages, labor, <i>et cetera</i> ,	2,000
Freight and incidental charges,	2,182

£11,717

PRODUCE.

365 tons of sulphate of ammonia, at £12 per ton, ..	£4,380
255 tons of acetate of lime, at £14,	3,570
19,000 gallons of naphtha, at 5s.,	4,750
109,500 pounds of paraffin, at 1s.,	5,475
73,000 gallons of volatile oil, at 1s.,	3,650
36,000 gallons of fixed oil, at 1s.,	1,800

23,625

leaving a net profit of £11,908, or a fraction more than a hundred per cent. The cost of the manufactory for working such a quantity was stated to be about ten thousand pounds. That peat, and other substances heretofore useless, should be productive of a trade so profitable, was more than could well be credited by the parties wishing to embark in the speculation; and to satisfy themselves on this point, a series of experiments was instituted in the laboratories of the Museum of Irish Industry, under the superintendence of Sir ROBERT KANE and Professor SULLIVAN. These were conducted upon specimens of peat from various peat deposits in Ireland in a twofold manner: firstly, by distilling the peat in close vessels, and secondly, by effecting the distillation by a combustion of a part of the material with a blast of air, as proposed in the manufactory.

In operating by the former method, a retort was used similar to that employed in the distillation of coal in the manufacture of gas. To the exit pipe from this retort a series of WOULDIE's bottles were adapted, wherein the greater portion of the tar and other aqueous products were deposited, the remainder being condensed in a worm fixed in a barrel of water, and the permanent gases collected. In each trial one hundred-weight of peat was worked off in eight to fourteen charges, according to the density of the substance. The annexed table represents the quantity of the gross products obtained:—

No of Experiments.	Locality whence obtained.	Water.	Tar.	Charcoal.	Gas.
1.	Surface peat, } A mixture of about equal parts of the two peats, from }	23·600	2·000	37·500	36·900
2.	Dense peat, } Mount Lucas Bog, near Phillipstown,	32·273	3·577	39·132	25·018
3.	Light surface peat, from Wood of Allen,	38·102	2·767	32·642	26·489
4.	Black compact peat, from do.,	38·628	2·916	31·110	32·346
5.	Surface peat, from Ticknevin,	32·098	2·344	23·437	42·121
6.	Do. distilled with the retort heated to a very bright redness,	38·127	4·417	21·873	35·693
7.	Surface peat, from Shannon,	21·189	1·462	18·973	57·746
	Dense peat, from do.,				
	Average,	31·378	2·787	29·222	36·616

The amount of ammonia, acetic acid, and naphtha, as well as that of the oil and paraffin in the tar; the following table contains the results obtained:—

TABLE REPRESENTING THE PER CENTAGE OF AMMONIA, NAPHTHA, ACETIC ACID, PARAFFIN, AND OILS, OBTAINED BY THE DISTILLATION OF PEAT.

Locality whence obtained.	Ammonia.		Acetic Acid.		Pyroxylic spirit or naphtha.	Paraffin.	Volatile oil.	Fixed oil.
	Ammonia as NH_3 .	Corresponding quantity of sulphate.	Acetic acid as $\text{C}_4\text{H}_3\text{O}_3, \text{H}_2\text{O}$.	Corresponding quantity of acetate of lime.

Average,.....	0.181	0.702	0.161	0.236	0.119	0.112	0.647	0.266
	0.268	1.037	0.191	0.280	0.146	0.134	0.790	0.550

In the second series of experiments, in which the peat was consumed by igniting it, and then supporting the combustion by a blast, the same peats were used as in the foregoing tables. The annexed table shows,

however, only the products obtained from those which in the former experiments exhibited the greatest dissimilarity, this being sufficient for the purpose of comparison:—

Character of Turf, and Locality whence obtained.	Water.	Tar.	Ash.	Gases.
Light surface peat, from Wood of Allen,.....	31.678	2.510	2.493	63.319
Dense peat, do.,.....	30.663	2.395	7.226	59.716
Dense peat, from the River Shannon,.....	29.818	2.270	2.871	65.041

The amount of ammonia, acetic acid, naphtha, paraffin, and oils, obtained in the same way, and expressed in the following numbers, affords a comparative view of the merits of both methods of working:—

TABLE REPRESENTING THE PER CENTAGE OF AMMONIA, ACETIC ACID, NAPHTHA, PARAFFIN, AND OILS, OBTAINED BY THE DISTILLATION OF PEAT IN A BLAST OF AIR.

	Ammonia.	Acetic acid.	Naphtha.	Paraffin.	Oils.
Light surface peat, Wood of Allen,.....	0.322	0.179	0.158	0.169	1.220
Dense peat, do.,.....	0.344	0.268	0.156	0.086	0.946
Dense peat, from the River Shannon,.....	0.194	0.174	0.106	0.119	1.012
Average,.....	0.287	0.207	0.140	0.125	1.059

The average results of both methods of operation gave for the distillation in close vessels—

	Average.	Maximum.	Minimum.
Aqueous products,.....	30.614	32.678	29.818
Tar,.....	2.392	2.510	2.270
Gases,.....	62.392	65.041	59.716
Ashes,.....	4.197	7.226	2.493

The watery products and tar afforded—

	Average.	Maximum.	Minimum.
Ammonia,.....	0.287	0.344	0.194
or as Sulphate of ammonia,.....	1.110	1.330	0.745
Acetic acid,.....	0.207	0.268	0.174
or as Acetate of lime,.....	0.305	0.393	0.256
Naphtha,.....	0.140	0.158	0.106
Volatile and fixed oils,.....	1.059	1.220	0.946
Paraffin,.....	0.125	0.169	0.086

Placing these numbers in apposition, the following will express the relative value of the two modes:—

	Average produce from close distillation.	Average produce from distillation in blast of air.
Ammonia,.....	0.268	0.287
or as Sulphate of ammonia,.....	1.037	1.110
Acetic acid,.....	0.191	0.207
or as Acetate of lime,.....	0.280	0.305
Naphtha,.....	0.146	0.140
Oils,.....	1.340	1.059
Paraffin,.....	0.134	0.125

The similarity of these numbers shows that very little difference exists between the results obtained from the distillation of the substance in close vessels, and from its decomposition in the fire by a blast of air. In the first case, however, there remains an average of twenty-nine parts of charcoal, which might determine a preference for that method, were it not that the greater part of this is consumed in carbonizing the matter in the retort.

A similar and independent series of experiments was conducted by Dr. HODGES, whose results are appended

below, and contrasted with those arrived at by Professors KANE and SULLIVAN, as well as with those form-

ing the basis upon which the company's prospectus was founded:—

	Kane and Sullivan.		Hodges.		Statement in Company's Prospectus.	
	Per ton.	Per cent.	Per ton.	Per cent.	Per ton.	Per cent.

Products of {Paraffin,.....	2 $\frac{1}{2}$ “	0.125	—	—	3 lbs.	0.104
the tar, {Oils,.....	nearly 2 $\frac{3}{4}$ galls.	0.159	—	—	2 $\frac{1}{2}$ galls.	0.071

If the difference of the peat in these experiments be taken into account, the results of the three columns will be nearly equal; for in HODGES' experiments the peat was of a black unctuous nature, weighing, per cubic yard, from five and a half to six and a half hundred-weight.

At first, the apparatus erected for the distillation, *et cetera*, was on a small scale, and not so much with the object of realizing an immediate profit, as with a view to the perfection of the process by which the operation might be conducted on a scale of greater magnitude. During this preliminary phase of the undertaking, very little advantage accrued beyond opening the eyes of the conductors to the necessity of having some more perfect medium for condensation, and turning the inflammable gases to useful purposes, as also for purifying the products, and bringing them into marketable condition. It was necessary, therefore, under these circumstances, to erect new works; and, as many things had to be invented, this occupied considerable time. The factory has now been in active operation for some few years. The arrangement for the combustion of the peat consists of four furnaces, constructed like ordinary blast furnaces, and without gratings, but furnished with three tuyeres through which the blast enters. Each furnace is thirty-two feet seven inches high, from the ground to the top of the hopper; the hearth is three feet two inches deep, three feet wide, and eighteen

inches to the top of the dam-plate; the tympanum is thirteen inches high, and has two inches of water space; the boshes are seven feet six inches high from the bottom of the crucible part, and twelve feet wide at the belly; the cone or body is sixteen feet high, and six feet wide at the tunnel head. The base of each furnace is square as high as the belly, and the whole of the cone or body is covered with boiler-plate firmly riveted. Such a protection is necessary, in order to prevent a leakage of the products of distillation, besides giving greater stability to the erection. The top of each furnace is completely closed by a conical valve three feet in diameter, and surmounted with a changing hopper provided with two tight-fitting lids. This hopper is five feet high from the valve-opening to the lid, and eight feet in diameter at the top. Two pipes, each twelve inches in diameter, convey the products of distillation into an hydraulic main, three feet in diameter, whence the condensed tar and other liquids flow into a tank, while the gases are made to pass through two double rows of upright condensing pipes, twelve inches in diameter, and twenty-five feet high, including two series of rectangular boxes upon which they are fixed. During the passage of the elastic vapors and gases through these pipes, an additional quantity of tar and aqueous products is liquefied and collected in rectangular boxes placed in connection with the pipes, by an arrangement which will be further explained in the drawings annexed. After

Fig. 40.

the gases traverse the condensers, they are conducted through a series of eight scrubbers, twenty feet high, and arranged in four rows. Each scrubber has three layers of small stones resting upon gratings, and is besides fur-

nished with a mill and tumbler, by which a dense shower is made to fall through the scrubber. By this contrivance the gases are washed of all traces of tar and condensable matters, such as naphtha, *et cetera*. From the

scrubbers the gas flows into a kind of main called the trunk, twenty-five feet three inches in length, and three feet eight inches in diameter, and from which it is distributed to the several fire-places to be consumed under evaporating pans or boilers, as required.

Fig. 40 is a side elevation of this arrangement, represented, for want of space, as broken off in the middle. *A* is one of the four furnaces, a section of which, along the line *x*, is shown in Fig. 41; and Fig. 42 is a plan of the platform, *G*, on the top of the furnaces, with part of the condensing apparatus attached. The same letters in each of the figures indicate corresponding parts.

Referring, in the first place, to the sectional view of the furnace—Fig. 41—*a* represents the arrangement of the tuyeres, with their nozzles, showing the water spaces and the plug valves for allowing the

Fig. 41.

of cast-iron or other material to form the counterpoise.

The platform on the top of the four furnaces, part of which is represented at *G*, in Fig. 42, is constructed of planks of wood laid on the same plane as the covers of the hoppers. The dried peat or turf is elevated to this platform in iron waggons, each thirty cubic feet in capacity, by means of a water lift, consisting of a floor upon which four waggons fit, supported by a frame or cage with friction pulleys at the angles, for working against the four upright pillars of wood which support a framework at top, having a drum and brake. The flooring of the cage is attached to a chain which passes over the forementioned drum, and is counterpoised by a wrought-iron cistern, five feet square, and two feet six inches deep, provided with a valve in the bottom, with an externally projecting spindle. The peat is brought from the bog in flat-bottomed boats by the canal, which

terminates in a kind of basin, having a quay a few yards wide at the foot of the lift. Here the waggons are

Fig. 42.

filled with the turf, and they are then rolled in upon the floor of the cage previously let down to receive them. In this position of the cage, the counterpoise or cistern is at the top, and, while there, water is allowed to flow into it from the tank, *I*, which is in turn supplied by the feed-pipe, *J*, connected to a large pump worked by a steam-engine which drives the other smaller ones throughout the works. When the cistern is full, it more than counterbalances the weight of the cage and loaded waggons; and, accordingly, on letting go the brake, the former descends, and by means of the chain passing over the drum, draws up the cage and waggons to the level of the platform, *G*. When the cistern full of water reaches the ground, the projecting pin strikes against it, by which the valve is lifted, and the water allowed to flow out. The waggons full of turf are next rolled along tramways at each side of the hoppers, one of which is shown at *N*, to the furnace into which it is discharged. This part of the work is performed by rolling the waggon on to a turning table, *M*, situate at each side of the furnace, and there made to perform a fourth of a revolution, so as to bring the end of the waggon, which is provided with a hinge and latch, over one of the hopper lids, *H*; the latter is opened, and the turf discharged into the orifice. Three waggons full, or ninety cubic feet, fill the hopper, and this constitutes a charge. Whilst the hopper is being filled, the conical valve, *b*, is raised to the position in which it closes the furnace, as shown in Fig. 41, and none of the products of distillation can escape; but as soon as the hopper is filled, the lids, *H H*, are firmly closed, and the grooves into which the lid flanges are partly filled with turf dust and some of the blue clay marl underlying the peat bog, mixed up into a magma with water. This paste forms an excellent lute round the lid, which is kept tight by a latch.

The valve, *b*, Fig. 41, may now be lowered by the lever, *d*, which, while the valve is up, has its extremity bearing the counterpoise, *e*, hooked to the platform by means of the small aperture seen near the counterpoise; but when this is unhooked, the valve descends, and the turf falls into the furnace. This being effected, the lever is again hooked in the usual position, and the hopper recharged. In this method of working, the only loss sustained is merely the full

of the hopper of gases each time the furnace is charged. When light peat is burned, the charge weighs about seven hundredweight, so that it would require about a hundred and forty-three charges to burn fifty tons of material, and two hundred and eighty-six to burn one hundred tons, the work assigned to each furnace in twenty-four hours. Allowing one hundred cubic feet of gas to be lost at each charge, the total for each furnace during the day's working would amount to twenty-eight thousand six hundred cubic feet; but this is too high, for the average weight of a charge of the brown turf employed is about half a ton, and, therefore, only two hundred charges are required to perform the work, so that the loss is reduced in actual practice to twenty thousand cubic feet; and this quantity, compared to the total quantity produced, is very insignificant.

When the fire is lighted in the furnace, and the blast directed upon it, the part immediately ignited is resolved into the simplest and most permanent products of combustion; but as these ascend, the carbonic acid is resolved into carbonic oxide by the incandescent fuel overhead, and this gas, together with the nitrogen of the air, rises in a heated state through the mass. These superheated gases are the agents which effect the distillation of the great mass of peat in the body of the furnace, and carry the products off to the mains, as already intimated, by outlet pipes, C—Figs. 40 and 41—of which there are two to each furnace. These outlets are fixed near the top of the furnace; they consist of a short ascending and a long descending pipe, the angle where they meet being provided with a hand-hole for cleaning out, and which can be secured by a dog and screw. The long arm enters the hydraulic main, D, shown in section in Fig. 40, and represented as broken off in the plan, Fig. 42. This main is kept half full of liquid, below the surface of which the outlet pipes dip. Each furnace is thus isolated in the same way as the retorts in a gas factory. The hydraulic main consists, properly speaking, of two; the principal one running along the furnaces in front, and marked D; and, secondly, a cross piece, E, which connects the former to a shorter one, F. Both these are closed at the ends with plates of iron, which can be removed whenever they want cleaning. Overflow pipes, screwed to those plates, draw away all the tar and liquid which accumulate in the mains above the proper level; this excess is conveyed into a tank not marked on the drawings, but its place is indicated by x, in Fig. 42. Four ascending pipes convey the gas from the main into the condensers; each of these pipes is provided with a valve, w. As was already stated, there are two distinct series of condensers, each consisting of eighteen rectangular boxes, shown in section at U, Fig. 43. Upon the top of each of these are placed four upright pipes, and those of each series constitute two rows. The adjoining pipes in each row, belonging to different boxes, are connected by a breeches-piece, which has two openings in the top, closed by caps, dogs, and screws, p. The gas flowing through the valve, w, is thus enabled to ascend one pipe in a row and down the next, into the first rectangular box, thence up the next, and, by means of the breeches-pipe, into the adjoining condenser pipe and box, and so

on. A diaphragm, as seen in Fig. 43, separates the box into two compartments; this division is not perfect, however, for at the bottom a space is left, so that both form only one.

The four pipes open into one compartment, and as both are kept nearly half full of water, the gas entering into the side compartment cannot escape otherwise than by the pipes, unless the pressure is so very great as to force all the liquor out by v, into the next chamber. All the condensable matter that accumulates in the inner chamber soon finds its level in the outer one by the communication at the bottom of the box, and when it rises to a certain height in the latter, it flows out by a siphon pipe into a conduit in connection with the tank, x. All the boxes are in communication with one another by a short connecting pipe passing from one to the other near the bottom; the same level of liquid is thus insured in all. To prevent the condensing pipes ever getting too hot, a conduit, K—Fig. 42—in connection with the cistern, I, is carried along the top between the two rows, to each set of which it sends out an arm, L, pierced with small holes, which allow a fine stream of water to fall on the tops of the pipes, and to trickle down the sides, and thus cool them effectually.

Notwithstanding all the refrigerating surface afforded by the double line of condensers, a certain quantity of tar and ammonia, and the greater part of the naphtha, still remain uncondensed, and are carried forward mechanically by the force of the blast; and to guard against a loss being sustained, the scrubbers, Q—Fig. 40—have been appended. These are arranged in four rows, corresponding to the four rows of condensing pipes. Each scrubber consists of a cylinder of wrought-iron, four feet six inches in diameter, and twenty feet high, closed at both ends, and having three gratings in the interior, upon each of which is placed a layer of stones, shown at j, Fig. 44. The gas enters at M', and passes up through the layers of stones, while, at the same time, the mill, K', supplied with water from an inch pipe connected with K, Fig. 42, or with the tumbler, L', produces a dense rain by its revolution; and this shower meeting the gaseous bodies ascending through the layers of stones, completely removes all the considerable bodies remaining in it. The water which thus traverses the scrubber, and becomes partly saturated with tar, ammoniacal matter, and naphtha, flows off from the base by a pipe into a tank, not exhibited in the drawing, but which may be designated by z, Fig. 40. After passing through the first scrubbers,

Fig. 43.

Fig. 44.

the gas enters the second series by means of a pipe, and after it is washed in these, as described, it flows into a kind of gasometer, *s*, Fig. 40, consisting of a pipe twenty-five feet three inches long, and three feet eight inches wide, and kept full of water to the level of the line shown. By means of the valve, *w*, in the main, *r*, and the dip of the pipe, *r*, into the water of the gas-holder or trunk, *s*, each row of condensers, and each pair of scrubbers, may be isolated, and the gas shut off from them whenever they require cleaning.

As the whole of the water which passes through the scrubbers must be distilled in order to obtain the ammonia and naphtha which it has absorbed, it is found desirable to make the same liquid serve two or three times for washing the gas. This is done by placing barrels, *t*, on the tops of the scrubbers, *q q*, and pumping into them from time to time a portion of the liquor from the tank, *z*. Each barrel supplies liquor to four scrubbers, by means of branching pipes.

Owing to the retention of the tar by the layer of stones, the scrubbers would get clogged from it, were there no provision made for cleansing them. The means adopted is to inject steam into them once in the day, by which the tar is melted, and in this state flows out at the bottom of the tank. From *s* the combustible gases are carried off by a duct, from which, by other channels, it is taken to the several flame-beds, where it is consumed.

Such are the principal details of this manufactory, having in view the recovery of the volatile products of distillation only, the charcoal which the peat would afford being entirely burned.

The high heating power of peat-charcoal, as well as its disinfecting and other qualities, invest it with peculiar interest to the smelter, the sanitary reformer, and the agriculturist: for the former it has long been productive of great advantages, more especially in the manufacture of iron, and therefore its production, on the most economical scale, and in the largest quantity, has been a subject to which some attention has been paid. This is more particularly the case in Bohemia, Bavaria, France, Russia, and other countries, where it is used in the blast-furnaces of their iron-smelting establishments, and produces very satisfactory results. In the numerous other processes to which the metal is subjected, the charcoal is found quite as efficient, if not more so, than wood-charcoal. In England, however, where coal is so abundant, a material which is at her command in as great abundance as her coal, has been allowed hitherto to remain useless; but it is to be hoped, that the success which has attended its application in the particular instances alluded to, and the free discussion of its advantages which one now meets with, will remove any prejudices existing in the minds of manufacturers against its employment. At present, or at least till within a recent period, the cost of the product has been very high, in fact out of all proportion when compared to that of other kinds of fuel; and this, perhaps, has been one cause why it has not been extensively consumed in smelting and other works: but if, by the attention of manufacturers, the charring of peat had been understood, and conducted on such a scale as would bring its marketable value on a footing

with that of coke, there is little doubt of its very soon being introduced into several establishments from which it is at present excluded. When peat is acted upon by heat in close vessels, it yields a variable amount of charcoal, from twenty-five to forty per cent., according to its density and state of dryness; but, as it is rarely distilled in this way, the quantity obtained is from twenty-five to thirty per cent., and at best does not exceed thirty-five per cent. The methods followed for the charring of peat are, in some respects, similar to those already described as being pursued in carbonizing wood on the large scale; these are the meiler system, and that by the furnace. For operations by the first of these methods, the nature of the peat and the regular form of the sods or bricks offer advantages for constructing the heap more regularly, leaving less interstitial space than the logs of wood, and, being less combustible than the latter, the process does not exact that minute attention which the carbonization of wood requires. It is necessary that the peat should be thoroughly desiccated, otherwise the charring will proceed irregularly, and sometimes not at all. Large quantities of peat are carbonized in this way in the Vosges, in Bavaria, Saxony, and Bohemia. In these places, one or other of two forms of constructing the meiler is adopted—either the circular or bee-hive, so frequently resorted to in charring wood, or the rectangular one. At the Royal Iron Works of Weierhammer, in Bavaria, where the refining and puddling of iron has been carried on since 1838 by means of peat-charcoal, the peat is charred in the circular mound, prepared almost as in manufacturing wood-charcoal.

A level site being chosen, a stake or quandel is fixed in the middle of a circular space, and round it on the ground a quantity of brushwood is spread, and which in turn is covered with waste charcoal from a previous operation. The turf is then piled round to the extent of the base, and to the proper height, preserving the conical shape. Generally, the size of the heap is about two thousand five hundred cubic feet, or thirteen and a half tons of the peat of the locality. When the central stake is withdrawn, brushwood is introduced into the opening and ignited. This communicates fire to the surrounding mass, which, in turn, conveys the heat towards the exterior. Owing to the closeness with which the turf admits of being packed together, the carbonization would proceed but slowly, were it not that air-channels of the breadth of a single brick of the peat are constructed at regular distances, and radiating to the circumference of the meiler. A covering of moss and leaves is placed upon the body of the heap, and outside this another of sand and turf ashes, or charcoal dust, is thrown on, leaving the upper part open, as a kind of chimney for the passage of the gaseous products, till the mass has been thoroughly ignited. As soon as flame appears at the top of the heap, a covering is thrown on, and the contraction of the mass observed, so as to keep any breaks occasioned by the sinking renovated. The charring is conducted regularly in the whole meiler by closing the draught-holes at the base, where the combustion becomes too vivid, or boring a few about a foot asunder in the upper part, where the progress is slack. Twelve to fourteen

days are necessary to char and cool a meiler of the above size, so as to be fit for removal. About seven hundred cubic feet of charcoal are obtained, weighing about three tons eight hundredweight, or 27·7 per cent.; hence, somewhat less than four tons of the peat of the district yields one ton of charcoal.

In Saxony, the rick or rectangular system is adopted, and the results are good. The ground is levelled and covered with sand in the usual way, and afterwards the rectangular space marked out; this is about fifty feet long by five or six in breadth. The middle of this plot is hollowed out into a kind of basin, and from it two channels or drains are cut from the ends of the intended heap, but inclining towards the central cavity. Both channels and well are constructed of, or are lined with bricks, a layer of clay being laid beneath, so as to prevent any fluid products collecting therein from percolating through the soil. A small gutter leads from the cavity in the middle to a tank at a little distance, where the liquids are recovered. These necessary constructions being made, a number of quandels is fixed in the longitudinal channel, ten feet apart, and the peat heap constructed to the height of four feet, leaving transverse channels corresponding with the vertical one which the stake forms. When finished, the quandels are withdrawn, and the whole coated with a mixture of clay, sand, and chopped straw or grass, the latter being used to prevent the luting from cracking. This mixture is prepared in two boxes or pits, one at each side of the mound, and quantities of it are always at hand so as to be available for stopping any cracks which might present themselves during the charring. Ignition is commenced at each end of the rhomboid by a fire placed in the central channel; the brushwood with which this has been filled burns, and, in doing so, sets fire to the surrounding peat. When the turf is fully ignited throughout the whole mass, a thick black smoke issues from the chimneys; as the carbonization proceeds, this becomes lighter, assuming gradually a greyish-white color, and finally changes to a bluish shade as the moisture evaporates. At this state, sulphurous acid becomes disengaged. As soon as the whole of the moisture is dispelled—a fact ascertained by holding the hand in the vapor as it issues from the chimneys, and observing if condensation takes place—the fire is gradually smothered by closing the air channels and fire flues. Care is also required in the management of the draught, so as not to allow of a consumption of charcoal taking place; generally, the apertures on the windward side are kept closed, the opposite ones being sufficient to supply air. The charcoal prepared in this way is of excellent quality, and much used in the metallurgical establishments of Saxony and Bohemia.

Both these systems of charring peat afford nearly the same yield of charcoal, when the operations have been properly attended to. It ranges from twenty-four per cent. by weight and twenty-seven by bulk when the peat is not thoroughly air-dried; but if this condition has been attained, the product is about twenty-seven per cent. by weight, or thirty-two and a half by bulk: a larger produce is occasionally obtained, but in those cases the exception must be attributed to the density and dry-

ness of the material before carbonization. The cost of a ton of charcoal at Weierhammer, manufactured by the process described, is about sixteen shillings and twopence, the peat from which it is produced having a marketable value of two shillings and elevenpence halfpenny per ton: allowing that four tons of peat are required for the production of one ton of charcoal, it appears that the charring expenses for one ton of charcoal are about four shillings and fourpence. In the neighborhood of Carolinen Hütte, near Achthal, in Styria, where some successful attempts have been made to smelt iron with peat in its raw state, mixed with wood, a ton of peat-charcoal costs twenty-two shillings and sixpence; but of this, eighteen shillings and twopence form the cost of the material, so that, practically, the charring expenses are the same as at Weierhammer. Such is also the cost of carbonizing by the meiler or rick system in Saxony.

Partly from the fact that less labor is required in managing the operation, whilst a regularity in the produce is, in some measure, insured, and partly from the circumstance that there always exists a supply of material at hand in every peat district, which would render the expense of removal of furnaces unnecessary when once erected, the system of charring in kilns has been resorted to with advantage. Furnaces or kilns are employed near Meaux in France, in East Friesland, and Bohemia, to a considerable extent.

The furnace or kiln employed for this purpose at Oberndorf, in Wurtemberg, is represented in Fig. 45. It is an upright cylinder, nine feet high and five and a half feet in diameter, having a capacity of about two

Fig. 45.

hundred cubic feet, and capable of distilling about four tons of average peat; the top is closed by an arch, with the exception of an opening, *i*, through which the peat is introduced; it also answers the purposes of a chimney till the charge is carbonized. A double line of construction is adopted in the erection of these kilns; an inner one, *b b*, of firebrick, and an outer one, *a a*, of more common material: both are about fifteen inches thick, and between them is an interstice, *c c*, of the same width, excepting where the brickwork extends the

whole breadth, as at *d d*, for giving greater firmness to the construction. The superior aperture, *i*, is closed by a tightly-fitting lid, *k*, when necessary; at the base is another door, closed by a cast-iron plate, *f*; and behind this is a space, *m*, formed by the door and the plate or board, *e*, and which is filled with sand through the aperture, *g*; thus the draught is effectually cut off at this orifice. There are three tiers of holes, *d d d*, formed at a short distance from the base of the furnace, through which air enters for supporting the combustion of the peat during the carbonization, as long as this takes place. In working this kiln, the peat is thrown in at the top and packed closely, with the exception of a few channels left free, corresponding to the lower draught holes, and also a vacant space in the centre; after being filled, fire is thrown in from the top, and the orifice in this part left open; when the fire has spread through the mass, so as to present a glowing appearance on being viewed through the lower apertures, these are closed with clay stoppers, and the combustion allowed to proceed till the same appearance is observed on looking through the second holes, when these are likewise stopped; and when the mass appears white hot at the third row of perforations, and no more smoke appears, all the apertures are secured, and the mass is allowed to remain till cold. Forty-eight hours are occupied in bringing the mass to incandescence, and after that seven or eight days are required for the cooling of the furnace. To avoid this delay, it is customary to have a damper plate situated in the bottom of the furnace, under which is a pit, so that, on withdrawing the damper, the red-hot charcoal falls into the pit, and the furnace is ready for a fresh charge. Sometimes the furnace is so constructed as to enable the manufacturer to recover some of the products of distillation, and use the combustible products for heating the mass of peat. In these, a pipe leads from the shoulder of the arch to a kind of condenser, where the ammoniacal and tarry matters are retained, and the gaseous bodies are reconducted by pipes to the bottom of the furnace, where they are burned under a grating, and serve to ignite the charge. No delay, or at most

only an inconsiderable one, takes place in the charring with the latter kind of furnace, and the product is satisfactory in relation to quality and yield.

Of this description are the kilns used at Crouy-sur-l'Ourcq, near Meaux, one of which is represented in Fig. 46. In this kiln the carbonization is effected in a cylinder, *a*, heated exteriorly by the flame and heat from the fires, *c c*, which circulate in the spiral flue, *b b*; *d d* is a chamber, encircling the walls of the flue, wherein air is

confined, with the view of retaining and equalizing the heat. The peat is introduced into the kiln by the aperture, *e*, at the top; this aperture is closed when

the charring is going on, by an iron plate, *f*; the products of the combustion going on in the fires, *c c*, issue by an opening, *g*, in the top, and those of the distillation of the charge by a pipe, *l*, connected with a condensing apparatus of the usual construction, and in which the liquid products are retained, the uncondensed gas being conveyed back to the fires, where by their combustion they serve, in part, to maintain the proper degree of heat. When the carbonization is completed, the charcoal is removed by the channel, *h*, by drawing the plate, *i*, which serves as the bottom of the kilns; it then falls into the chamber, where it is allowed to cool; from thirty-five to forty per cent. of charcoal is obtained, according to the density and state of dryness of the crude fuel. The cost of charring by this furnace is estimated at an average of four shillings per ton of charcoal.

Somewhat differing from the latter in construction, though worked upon the same principle, is the peat-charcoal furnace of East Friesland. It has a solid base sixteen feet long, thirteen wide, and two feet thick; upon this base an oblong furnace is erected, twelve feet long, five wide, and eight and a half high. The end walls of this construction are two feet thick, but the sides are only six inches; parallel with the side walls, and at a distance of eighteen inches, two others are built, each two feet thick, and the end ones are continued at both sides to meet them. By this arrangement a space is enclosed between the interior construction, or the retort, and the exterior wall, and this space serves for the fire channel, in which the products of combustion, from a fire lighted in a hearth, one foot high and eighteen inches wide, with grate and ashpit, made at one end of each of these chambers, circulate for the purpose of heating the retort. An arch or dome completely encloses the inner chamber destined to carbonize the peat; another similar arch is sprung from the outer walls, thus encasing the top of the retort as well as the sides. At the end where the fires are situated, a charging door, five feet high and three wide, is situated, and this, when the process of charring is going on, is kept tightly closed. The floor of the inner retort is hollowed in the middle along the whole length, and the channel thus formed walled by a glazed clay gutter, and covered over with perforated tiles, the whole slightly inclined towards one end. The tar and other fluids which accumulate here during the carbonization, are carried off by a pipe to a tank at a short distance from the retort, and the uncondensable gases conducted back by other pipes to the furnace, where they are burned. For the sake of economy, two or more of such furnaces are built close to each other, by which the time of charring is shortened, less heat being allowed to escape. Such a furnace is capable of producing one ton of charcoal at each operation, at an average expense of four to five shillings.

Another furnace employed in Bohemia is the following:—A circular excavation six feet deep and twenty in diameter, is made, and the base lined with brickwork nine inches deep. Upon this the walls of the furnace are constructed, so that when completed the whole forms a frustrum of a cone. For this end, the walls are five feet thick at the base, and tapering, till, at the height

Fig. 46.

equal from seventeen to twenty-two shillings per ton. To prepare the peat, the patentee piles it, after being cut, upon wicker hurdles, one above another, and allows it to remain in this state till dry. The yield of charcoal is stated as from thirty-three to thirty-six per cent. —*Journal of Industrial Progress.*

VIGNOLES has taken out a patent for drying, compressing, and carbonizing peat, the latter being effected by means of steam heated to 450° or 460° Fahr., and the two former by a hydro-extractor, in which the centrifugal force expels the water, and renders the mass denser at the same time. With reference to the charring—the peat dried in the air, or by a current of heated gases forced through a chamber containing it, is thrown into cylindrical vessels, into which steam at a high temperature is forced, till the charring is effected. Fig. 49 shows a vertical section and partial elevation of the apparatus. In this, *a* represents a section of

Fig. 49.

the boiler employed for raising the steam; it is placed over a furnace, the flues of which, after passing under the boiler, branch off and circulate round the carbonizing cylinders, and finally enter the chimney. Two of the charring cylinders are shown at *bb*, of which there are six at each side of the boiler; they are ranged round a coil of piping, *h*, in which the steam from the boiler is heated to the required degree by a fire, previous to its passing into the cylinders where the peat is charred, by means of pipes connecting them. After the steam traverses one of these carbonizers, it escapes by a pipe, which conducts it over the furnace, to raise its temperature previous to its passage through the next carbonizer in the series. In this way, the steam being first heated is made to traverse a carbonizing vessel and the heating pipe successively, till it passes through the whole of the charring vessels. Ultimately, the waste steam is made to work a low-pressure engine, which turns a fan that forces air, heated by pipes placed in a furnace to 250°, into the drying chamber where the peat is desiccated.

The carbonizers, as may be inferred from the drawing, are conical towards the bottom, and are furnished with a valve or door which is rendered steam-tight, but may be opened when the charring is completed, so as to allow the charcoal to fall into a box, *p*, beneath it, and into which low pressure steam is passed for the purpose of cooling the charcoal. These boxes are constructed of iron, and are well covered, lest the charcoal might spontaneously ignite, to which it is liable, if exposed to air at this temperature; they move on tramways, and can be drawn out when required through the door-ways, *cc*. The top of the cylinder has a similar

opening secured by a screw; through this aperture the charge of peat is introduced.

Several other patents have, within the last few years, been secured by parties for economizing fuel, but to dwell further upon them would be out of place, as many of them come within the range of processes for the manufacture of artificial fuel, more than for preparing the peat alone in an improved state. That of Mr. P. M. CRANE, from its simplicity and its connection with the process already detailed, as pursued by the Irish Peat Company, will be briefly explained. The improvement to be noticed in this patent is the annexing of another furnace to that in which the combustion of the peat was effected in the above-mentioned Company's works. In this appended furnace, the peat is consumed by a blast of air in the ordinary way, and the torrefied gases are conducted by a flue to the second one, which is likewise filled with peat, and the heat thus communicated chars the matter.

In this way charcoal may be prepared without any loss of the products of distillation, as both furnaces may be closed down in the manner described in Fig. 41. The appended hearth or furnace may be modified, so as to enable the manufacturer to burn coal or coke, or even the waste gases formed in the distillation of the peat, turning the caloric and heated products which they yield to the use

mentioned.

Fig. 52 is a sectional drawing of one of CRANE'S furnaces for preparing charcoal by the combustion of peat alone. In this drawing, *AB* is the furnace connected with another furnace or charring chamber, *CD*, by a flue, *G*. Both these are filled with peat, and closed down in the manner described at Vol. II., page 60. The furnace, *AB*, is lighted, and the blast of air thrown upon the ignited fuel through three tuyeres, *ccc*, at the bottom. The heated gases are forced over into the furnace, *CD*, and passing up through the peat, char it. All the products—as well those from the combustion as from the charring furnace—are carried

Fig. 50.

Fig. 51.

Fig. 52.

off by the exit pipes, *fff*, to the mains and condensers in the usual manner. When the peat in the charring furnace becomes carbonized, the charcoal is drawn out at *E*, into covered tanks, or cast-iron boxes, in which it is allowed to cool out of contact with air. According as the peat becomes consumed in the first, or the

charcoal is withdrawn from the second furnace, the space rendered vacant is filled by charging the hoppers, *a a'*, and letting this charge into the furnaces in the usual way. Figs. 50 and 51 show the construction of the furnaces intended to consume coal, or anthracite, and gas, for the purpose of generating heated products for distilling peat. Fig. 51, for coal, needs no explanation, as its operations are similar to the foregoing. When gas is employed, it is conducted to the hearth, *Δ B*, by the flue, *I*, Fig. 50, and, being ignited, a blast of air is introduced by pipes communicating with a blast-pipe, *H*. The pressure of this blast forces the heated products through the carbonizer, *C D*, producing the intended results.

Such are the methods in common use where the preparation of peat-charcoal has been industriously pursued, and some of them offer considerable advantages. Of the analyses of peat-charcoal little need be said here, as the analyses of peat already given will throw some light upon this part of the subject. As a generator of heat, good peat-charcoal is as efficient as bituminous coal; and some varieties are even above the average heating power of the latter kinds of fuel.

COAL.—This is by far the most valuable and extensively disseminated fuel, or source of heat, and is defined by REDFERN—*a compressed and chemically altered vegetal matter, associated with more or less earthy substances, and capable of being used as fuel.* This definition expresses all that is necessary; but its truth can only be established by the concurrence and aid of several branches of knowledge. For instance, *animal* matters may, by a process of decomposition, yield a mass of carbonaceous substances, which could not be distinguished from similar vegetal ones by the naked eye. In such cases, the microscope and chemical analysis lead to a certainty as to the nature of the originals; the former by revealing the texture of the fibrous matter of the plant, and the latter by the separation and estimation of those bodies into which it has been partly resolved. Before giving any detailed account of the process by which coal has been produced, it may be well to explain briefly the proofs which are cited in argument to show what coal is; and for much of what follows on this point, the Editor must acknowledge himself indebted to the treatise on *Fuel and its Applications*, by RICHARDSON and RONALDS.

Evidences of the origin and character of coal may be gathered from the geological position of the deposit, the mineral characteristics, the chemical nature, and the visual appearance of the substance under high magnifying power. It is the opinion of geologists that coal may be viewed as a stratified rock, in which layers of other geological formations—such as clays, sandstones, and limestones—are found. These, in themselves, form vast deposits, or strata; but, in this respect, there is no difference between them and the coal-beds, excepting in the nature of the substances. How the matter has become so stratified, is a question to be afterwards considered. The coal seams vary from a mere film, or a layer of less than a quarter of an inch in thickness, to three or four feet. It is not often, however, that the deposits are of the latter dimension. In mines, where the depth of the carbo-

naceous deposit averages from ten to twenty or thirty feet, seams of mineral matters interpose themselves at intervals, varying as to the distance between them, but rarely exceeding the limits above assigned. All coal-beds contain these foreign strata, or *partings*, to a greater or less extent; they seem to have been the result of the precipitation of matters held mechanically suspended in water. The thickness of these intervening deposits is found to vary considerably from a mere seam to a bed of several feet. In many cases the mineral matter, thus interstratified, has become so saturated with bodies emanating from the coal, or during its formation blending with the carbon, that it ignites and burns like coal, only that its bulk of earthy substances remains, often retaining the original form. Such matters are frequently observed in the burning of many varieties of coal, and in common language are called *slates*, *batts*, or *basses*. This blending of the two substances is often so unmistakable, that at a glance it may be ascertained whether the *shale*, as it is called, is argillaceous or calcareous; but when it is known that the coal-beds belong to the alluvial deposits, it will be evident that the intermixture of mineral and organic matters must have proceeded collaterally, even although the latter appears in such excess as completely to obliterate any traces of the former. In Great Britain, coal is principally in the carboniferous formations, occupying a posterior place in the series of stratified rocks; and where the same stratification of limestone rocks is met with in other countries, beds of coal are generally to be encountered. Still coal is not confined to this set of rocks; it is found in different parts of the strata, from the Devonian down to the most recent tertiary formations.

Mineralogical Characters.—Although here the subject under consideration is spoken of as a mineral, it ought to be remembered that, strictly speaking, it is not a pure one, but a mixture of various matters, of which carbon is the principal. It may, however, be regarded as organic matter *mineralized*; and, as it manifests some of the general properties of minerals, these will be noticed. The several known varieties of coal possess each some distinctive feature, differing from one another in hardness, fracture, *et cetera*. Several species break up into cubical and rhomboidal fragments; whilst others—such as the anthracite—are nearly devoid of crystalline structure. Generally, the fracture is conchoidal, uneven, fibrous, or slaty; in Boghead coal the fracture is conchoidal, perpendicular to the plane of stratification, but slaty when parallel. In color, it presents according to the variety every difference of hue, from jet-black to brownish-yellow; many kinds have a glossy brilliancy; others—such as the varieties of anthracites—a beautiful semi-metallic iridescent lustre; whilst some—such as the Wemyss, Methil, and other varieties of cannels—have a dull appearance. Coal exhibits great differences in point of hardness, although none of the varieties possesses it in an eminent degree. Anthracite has a specific hardness of two to two and a half. The gravity of several kinds of coal differs according to the texture and age; the lightest kinds have a density bordering on 1·00, whilst the heaviest range from 1·75 to 2·00.

Chemical Characteristics.—From what has been stated, it is evident that a chemical examination of coal would, in the simplest manner, lead to its division into inorganic and organic substances, and that these are contained in it in variable proportions: and, further, that each of these classes can be resolved into other substances, the most characteristic of coal being those generated by the vegetal portion. This arises from the large proportion of the elements always found in it—namely, carbon, hydrogen, and oxygen; and which, by the action of heat out of contact with air, are converted into numerous and peculiar substances.

Distillation in close vessels resolves coal into solids, liquids, and gaseous bodies, consisting of carbon or coke, tar, ammoniacal liquor, benzol, naphtha, naphthalin, paraffin, paraffin oil, and illuminating and other gases, in various quantities. By the detection of these, and the proportion in which some are contained in the substance, a good inference may be drawn as to whether the body be coal or otherwise: nevertheless, the evidence is not so conclusive as when the investigation is conducted microscopically.

Microscopic Characters.—By the use of the microscope, the most conclusive proof of the origin of the coal is attained. Dr. AITKEN of Glasgow has carefully investigated the structure of coal, and found that, even in the most altered specimens, traces remain sufficiently characteristic to prove that the material is of vegetal origin.

In the variety of bitumens, whether pure mineral tar, or asphaltum, no such structure is observable, and consequently, in the hands of a chemico-microscopist there is nothing to render the detection of real coal a matter of uncertainty.

Origin of Coal.—Such being the principal or more marked characters by which a substance submitted to examination may be affirmed to be *coal*, it will now be desirable to enter more fully upon the origin and nature of this product, in reference to its value as a fuel. Allusion has already been made to the analogy which exists between peat and coal, and the reader will have inferred that coal, like peat, has been produced by the decomposition of species of organic growth. All who have given attention to the composition of coal, and the geological position it occupies, concur in this view of the subject; and the Editor will now explain briefly the different opinions advanced as to the manner in which the change and disintegration of the vegetal products have been produced.

It may be said that the process which has operated to convert countless reproductions of plants into peat bogs, has been similar in the case of coals to some extent; but, geologically considered, it is evident that the oldest peat deposits are of modern formation, when compared to the most recent beds of coal. Of the vegetal origin of the latter, no doubt can be entertained, even if the microscope had not revealed the fact in the more compact varieties, since among other indications, even the trees have been found in their natural position converted into coal. The character, the variety, and the immense mass of vegetal matter thus converted, have led to the conclusion that the several species of plants whence coal has resulted were indigenous to a

southern or equatorial climate, as it is certain they could not flourish so luxuriantly in the existing temperature of northern latitudes. The varieties most commonly distinguished in the different strata are ferns, calamites, sigillariæ, stigmaria, and others; in fact, no less than three hundred distinct kinds have been detected.

As to the manner, however, in which the strata of the coal deposits have been formed, there is much difference of opinion. Some geologists suppose that they were originally peat, the several successive layers being occasioned by successive subsidences of the land; whilst others assert that the various constituents were originally conveyed by currents to estuaries and deltas, where, being buried under the sand, mud, and debris brought down by the current, they were subsequently submitted to agencies which effected their carbonization. It is certain that the surface of the globe was at one time nearly submerged in an ocean, in which state it remained till, by the effects of volcanic eruptions, portions were uplifted, causing a corresponding depression in other places, and thus forming valleys, the forests and vegetation of which were buried under layers of loose earth and mud. At the same time, it would require many such forests to constitute a layer of the thickness of some of the coal seams, and these can scarcely be imagined to have been produced otherwise than by the drifting of vast accumulations of trees and plants into the basins in which coal is now found.

But leaving geologists to discuss and settle these questions, it is more in accordance with the plan of this work to attend to the chemical changes which have contributed to the conversion of the organic fibre into the carbonaceous matter in question. Whether the organic products on the surface of the earth were collected by changes in the relative position of the earth's solid crust, or by the force of violent currents, such as the large American rivers of the present day, it may be admitted and assumed as a fact that they were embedded with other matters saturated with moisture. The first natural change under such circumstances would be a fermentation of the albuminous matter and the gum, by which their molecular constitution would be broken up, and bodies of a simpler composition formed. The exclusion of the air after a short time would suppress the *eremacausis* or decay of the substance of the wood and fibrous matter, but the equilibrium of the affinities of the elements in the plants being broken, and considerable pressure being exerted, coupled with a certain rise of temperature, the change of elements arising from the new elective affinities would contribute to remove the hydrogen and oxygen to that extent which is observed in the composition of coal. The oxygen and hydrogen being most subject to the effect of this metamorphosis, these elements, leaving the carbon, would more readily assume their simplest and most permanent state of combination; but, as in the process of destructive distillation already alluded to, the conditions supplied are capable of inducing the water thus constituted to react upon a portion of the carbon, so in the coal formations, where the enormous pressure must have operated with an effect

in some degree equivalent to an increased temperature, the moisture and excess of hydrogen would convert the remaining substance into carbonic acid and carbides of hydrogen respectively. The actual facts, as determined in coal mines, seem to bear out this view.

From such considerations it will be readily concluded that the elementary composition of coals must be different from ligneous fibre; but following up the assumed alteration by a symbolical representation, the composition of coal offers very conclusive grounds to warrant the opinion that the former has resulted from the latter in the manner indicated. For instance, the composition of woody fibre may, as already stated, be represented by the equation $C_{36} H_{22} O_{22}$; and if, by the change above indicated, three equivalents of carbonic acid be extracted, represented by $C_3 O_6$, there results $C_{33} H_{22} O_{16}$; and if from this one equivalent of hydrogen be taken away, represented by H, there is left a formula— $C_{33} H_{21} O_{16}$ —corresponding with the composition of a variety of coal worked in Laubach.

In like manner the formula of splint coal may be deduced from the elements representing woody fibre, by supposing that the combined agency of heat and pressure removed nine equivalents of carbonic acid, three equivalents of water, and three of carbide of hydrogen, thus:—

According to the degree of force exerted upon the decomposing substance, and the period of time in which this change was taking place, it is evident that the substances would be more or less removed from one another in composition. In the first example stated above, the formation bears every indication of recent production, when compared with the second; and this accounts for the close analogy between the two formulæ of wood and that species of coal. In other kinds, such as many of the anthracites, the alteration is much greater than even in the splint already referred to, and it is much more difficult to recognize the analogy between them and wood, for often all the oxygen and hydrogen are removed, so that nothing is left but carbon and the mineral matters intermixed with it.

Coal Measures.—The region of the coal formations is very extensive, and includes many strata, all of which are known as the *coal-measures*, or carboniferous group. Properly speaking the first of these is what is termed the *under-lay*; this is, a tough argillaceous substance, which, upon drying, turns grey and becomes friable. It retains considerable traces of carbonaceous matters. Two other strata beneath this are, however, included in the group; these are the mountain limestone, which varies very much in thickness, being sometimes nine hundred feet, and the old red sandstone upon which it rests; the latter stratum ranges from two hundred to two thousand feet in thickness. Next to the underlay in the ascending scale comes the seam of coal, or modified organic matter, varying from less than a quarter of an inch to several feet. Above these the upper layer or roof, as it is termed, rests. It is composed of slaty clay abounding in vegetal remains, as well as with crustaceæ, and several other matters. Interstratified with the latter are found various other substances, which seem to have been accumulations drifted by currents, such as laminated clay, grit, limestone, granite, sandstone, and other rocks.

All these deposits at one time, doubtless, formed regular horizontal layers, but through the effects of expansion in the depths of the earth, they have been distorted and thrown into undulated positions, and where the internal force has been very great, they have, by the upheaval of the subordinate strata, been formed into large valleys or basins. From the position of these layers, previous to such convulsions occurring, it is obvious that as the older deposits of mountain limestone, old red sandstone, *et cetera*, emerged in succession, so the more modern layers, including the carboniferous, would appear at the surface. This appearance is termed the cropping out of the strata, and serves to indicate the side of the basin. Considerable irregularity is occasioned by further subterranean disturbances which tend to alter the position of the strata subsequently to the first upheaval of the older formations. These generally render the deposits somewhat irregular in shape, so that they seldom form a true basin. In some localities, as in the Leicester and Warwickshire coal-field, none of the characters of a basin are observed; in the latter instance, the seams are surrounded on all sides by overlying deposits, under which they dip or incline to a considerable depth, and extend to an area unknown.

Fig. 53 represents this field in section, showing the alluvial deposits at A A; the new red sandstone, or marls,

Fig. 53.

at B B; the carboniferous shale and coal at C C, interlaid with carboniferous grit, or sandstones, D D; E, beds of magnesian; and F the stratum of mountain limestone, resting on the old red sandstone, G. Fig. 54 gives a

faint idea of the disturbances which are occasioned in the various beds by fissures filled with other materials. These veins are, in the language of the miner, called *dykes*, as they are the means of separating the strata

into compartments, which are designated *fields*. Besides this term, another is applied significant of the displace-

ment of the bands of coal from their original position—namely, *shifts*. Where these occur, the seam is

Fig. 54.

thrown out of its level, and, according as it is removed to a higher or lower one, the fault is called an *up-throw* or a *down-throw*. The displacement occurring at many of these shifts is considerable, and gives no small trouble to the miners. The largest known is that which runs through the Northumberland and Durham coal-field, and is termed the Ninety-fathom dyke, from the fact that the seams of coal are ninety fathoms lower at one side of the slip than at the other. Various matters fill these intersecting veins; hard and soft sandstone is contained in the one in question, which in some parts, especially at the Montague Colliery, attains a width of twenty-two yards. Two other dykes spring from this at the Southern side; one of which takes a South-eastern direction, and is about twenty yards in breadth; the other a South-western one, and attains a breadth of seventy yards. Both branches are filled with the same material as the primary one, but do not appear to have caused so great a disturbance at their point of intersection. These are represented in the foregoing drawing at F F, S S; but the others, although they partake of the nature of a dyke, are not recognised as such. For instance, those shown at D D' are of a different character, and are called *whin-dykes*, containing products of igneous origin, such as basalt, toadstone, *et cetera*; these do not always cause a removal of the strata from the ordinary level. Evidence of their eruption in a state of fusion exists in the fact, that the coal in their vicinity is more or less charred and converted into a true coke; besides, many substances of a fusible nature are acted upon, and indicate the powerful temperature which has pervaded the place, and which is often productive of great loss by consuming or changing the coal into anthracite, as shown at D' in the figure, where the basalt and other products accumulate. The *hitch* is another of those dykes, and is so called when its thickness is less than that of the

seams of coal which it intersects: this is represented at H H in the drawing. Smaller veins of foreign matters lying in any direction contrary to that of the strata are designated *faults* or *troubles*, from the annoyance the miners experience by the interruption of their work. Several of these are seen at T T; and although in working they cause much trouble, yet sometimes they contribute to render a field more valuable, since, by the depression which they occasion, seams of coal are brought in which might otherwise be lost. An example of this is given in the drawing referred to, where, by the down-throw of the strata between F F and T T, two seams of coal are brought in which would not otherwise be contained in it. Other interruptions or irregularities in the coal seams are designated *bands* and *nips*; the former, shown at B, are thin deposits or beds of grit or shale occurring in the middle of a seam of coal, and which, from being very thin, gradually acquire greater thickness, till ultimately they reduce the seam so much as to render it valueless; the second, shown at N, is a sudden local thinning of the seam, from an excrescence of the roof or floor.

The distribution of coal is very extensive; it is found in almost every country, although to a very unequal extent. The United States may be considered as the most highly favored in this respect, if the area of their coal deposits be taken into account, irrespective of the extent to which they are worked. It happens, however, that, from the abundance of wood, the home consumption of the article is limited, while the conveyance is costly, so that the benefits which result from valuable coal seams in other nations, remain to be developed in America. According to the statistical calculations of MITCHELL, the annexed table represents the amount and varieties of the mineral coal treasures in the United States:—

TABLE SHOWING THE AREA OF COAL IN THE UNITED STATES OF AMERICA.

	Area of the State. Square Miles.	Coal Areas. Square Miles.	Proportion of Coal.	Species.
1. Alabama,	50,875	3,400	1-14th	Bituminous coal.
2. Georgia,	58,200	150	1-386th	"
3. Tennessee,	44,720	4,300	1-10th	"
4. Kentucky,	39,015	13,500	1-3rd	"
5. Virginia,	64,000	21,195	1-3rd	"

	565,283	133,132 nearly 1-4th the area of the twelve States.	

It is certain that this vast tract of carboniferous deposit is not in its whole extent calculated to yield workable coal; still, making every allowance for those parts which, from their thinness or depth, cannot be profitably worked, it is evident that the area is sufficient to insure, for an almost indefinite period, a superabundant supply. Although within the last thirty years the coal trade of the United States has increased from an annual produce of three hundred and sixty-

five tons to five millions of tons, yet it must be evident at a glance that this enormous source of wealth is permitted to lie comparatively dormant at the present day. In British America the coal measures are not so extensive as in the States; it is doubtful, indeed, whether any workable seams exist in Canada, but fields of considerable area are known in New Brunswick and Nova Scotia, making about two-ninths of the whole area; and Newfoundland is said to be rich in this mineral.

In the area of her coal deposits, Britain ranks next to the United States, and greatly exceeds the latter in the extent and value of her workable mines. The total extent of coal in England is estimated at about six thousand and thirty-nine square miles, or one-eighth of the whole area; in Scotland, one thousand seven hundred and twenty square miles, or one-eighteenth of the whole; and in Wales, one thousand one hundred and sixty square miles, or about one-sixth of its entire extent.

The principal deposit is that known as the great central coal-field, lying in South Yorkshire, Nottingham, and Derby; it is no less than sixty-five miles in length, and averages in some parts a breadth of twenty-five, making on the whole an area of about six hundred and fifty thousand acres. Next to this may be classed the Lancashire and Cheshire field, including the Wigan district; this deposit is about fifty miles in length, with an average breadth of ten miles, and is, therefore, no less than four

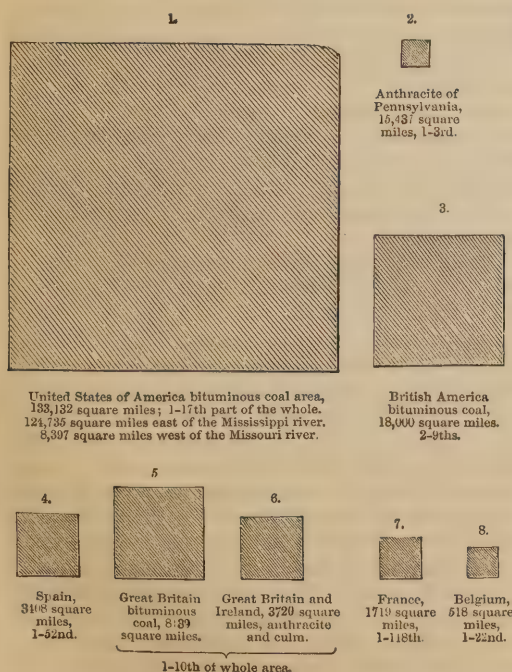

hundred thousand acres in area. Another field, which seems an extension of the latter, runs from its south-eastern extremity through Cheshire into Staffordshire, in which are the Cheadle, Macclesfield, and Pottery coal-fields. The third great deposit is that of Durham and Northumberland, which stands probably first in the list as to the quantity of fuel that is obtained from it. This vast deposit—called also the Newcastle coal-field—is estimated at thirty-six thousand acres situated in Durham, and about one hundred and fifty thousand acres in Northumberland. Of this extent about sixty-seven thousand acres are already worked. Estimating the content of this field at a thickness of twelve feet, each acre of four thousand eight hundred and forty square yards is supposed to yield a ton of coal per cubic yard, thus making the total weight of coals in this field about ten million tons, including the quantity destroyed and rendered unserviceable.

Besides the above, there are several other mines of secondary importance, from which a considerable quantity of coal is annually extracted. These, with their area, thickness, the number of workable seams, *et cetera*, are exhibited in the table in previous page, which is extended to embrace Great Britain and Ireland.

On the Continent the chief coal-producing countries are Spain, France, Belgium, and Prussia, although several others possess many valuable coal basins which hitherto have been little worked. The following diagram—Fig. 55—taken from TAYLOR'S work, gives a moderately comprehensive view of the comparative area of coal in the various countries that have been mentioned. It includes not only the workable seams, but the entire carboniferous area:—

DIAGRAM OF THE SUPERFICIAL COAL AREAS OF VARIOUS COUNTRIES.

Fig. 55.

It is evident, however, that this diagram, with its numbers, does not exhibit the relative value of the coal-fields in the different countries. This must depend on many circumstances, apart from the mere consideration of superficial extent; but their productiveness at the present day is shown in the next diagram—Fig. 56.

DIAGRAM OF THE RELATIVE AMOUNTS OF PRODUCTION OF MINERAL COMBUSTIBLES IN THE SIX PRINCIPAL COAL-PRODUCING COUNTRIES OF THE WORLD, IN THE YEAR 1845.

Fig. 56.

A summary of the whole, exhibiting at one view the extent of coal area, the quantity raised in 1845, with its relative proportion to the area, and, finally, the official estimated value of the places of production, is added in the annexed table:—

Countries	Square miles of coal formation.	Tons of fuel raised in 1845.	Relative parts of 1000.	Official estimated value of the places of production.
Great Britain, . . .	11,859	31,500,000	642	9,450,000
Belgium,	518	4,960,077	101	1,660,000
United States, . . .	133,132	4,400,000	89	1,373,000
France,	1,719	4,141,617	84	1,603,106
Prussian States, . .	not	3,500,000	70	856,370
Austrian States, . .	defined.	659,340	14	165,290
Total,		49,161,034	1000	15,108,729

It may be added, as the result of recent researches, that Asia and even Africa have been found to be very well stocked with fossil fuel; and, indeed, there can be little doubt that the East Indies and China will yet become coal-producing countries. The same may be said of Australia, and other British colonies.

DIFFERENT KINDS OF COAL.—From the acknowledged transformation which the substance of the coal has undergone, and from its progressive nature, it is natural to expect that the material so produced should have very different properties, according to its more or less advanced state of decomposition. Such is really the case, and various species of coal exist differing by slight and regular gradations from the most recent lignite or brown coal, in which the outline of the wood may be easily traced, up to the most perfect anthracite, in which every vestige of the original is lost, and nothing remains but a conglomerated charcoal. Many of them, indeed, have so close a resemblance to one another, and pass so imperceptibly from one stage to the other, that it is almost impossible to mark the distinction between them. Several species, however, may be classified on broader data, grounded partly upon age, partly on their physical appearance, and partly on their composition. It is by these criteria that the classification of the fossil into brown and black coal, or into the bituminous and non-bituminous varieties, is effected. Several members are contained in each of these groups, but many kinds blend with each other in such a manner that it is difficult to draw a line of demarcation between them. Classifying the chief varieties according to their supposed age, the whole of the coal measures may be included under three heads; namely, the younger coal of the *tertiary* deposits, the older bituminous kind of the secondary formations, and the anthracites of the older transition series of rocks.

Lignite.—The coal of the tertiary formation, which includes several varieties, has been designated *brown coal* or *lignite*, from its characteristic appearance. This species, termed also bituminous wood, is the most interesting, as clearly exhibiting the ligneous structure of the matter from which it derives its name, in such perfection as to furnish sufficient data for instituting a diagnosis of the plants of very remote eras. It has a brown color; but this varies with the depth of the bed. The Bovey coal of Devonshire is a member of this class; it presents a distinct woody structure, and very rarely a conchoidal fracture; it is devoid of lustre, is brittle, and burns readily, leaving a white ash. Some others, however, such as the more compact kinds, exhibit a more or less conchoidal fracture and slightly resinous lustre. In the latter case, the color is brownish-black; it has been

called earthy-brown coal, to distinguish it from another kind of the same species, designated *pitch-coal*, the structure of which is more dense, as shown by its distinct conchoidal appearance when broken. Between these extremes may be found the *brown earthy coal*, so named from its argillaceous fracture, crumbling into loose friable particles; and *moor coal*, in which the structure of the plants is obliterated, and which exhibits in its fracture more or less lustre.

The species of coal embracing these varieties is encountered in several of the formations on the Continent; at Bovey Tracey in Devonshire, near Lancaster, and at Lough Neagh in Ireland, where it constitutes three beds, averaging in some parts a thickness of sixty feet. It is very inferior as a fuel to the other varieties of coal which will be presently described. As dug from the mine it is more or less impregnated with moisture, which it persistently retains, and which, even if entirely expelled, is reabsorbed with great avidity. Thus REINSCH determined in a sample of wood coal from the Upper Pfalz, in Bavaria, forty-three per cent. of moisture, and in an earthy-brown coal, thirty. VARENTRAPPE found no less than forty-eight per cent. of moisture in fresh lignite from Helmstadt, and further ascertained that, after thorough desiccation and re-exposure to air, about eight per cent. of water was again absorbed. By stacking this coal for some time, much of the water evaporates, so that the moisture averages about thirty per cent.; but if the exposure be made in summer, the quantity is lessened to twenty per cent., the bulk of the coal undergoing a corresponding reduction.

Distinct from the foregoing in physical appearance, though to some degree analogous in chemical composition, are those non-compact bodies, termed bituminous coal, in which the structure of the plants is entirely effaced, and the color and appearance are indicative of a pretty advanced stage of decomposition. Of this kind there are several varieties, distinguished by characteristic properties. When treated with ether they all yield more or less bitumen, and hence the general designation, *bituminous*, to distinguish them from the anthracites proper, which afford none of that substance. The following most marked varieties of this description are *caking coal*, *splint coal*, *cherry coal*, and *cannel* or *parrot coal*.

Caking coal is a moderately compact fuel; its fracture is uneven, and its lustre varies from a resinous to a velvety or greyish-black appearance. When heated, it breaks into small pieces, if the amount of bitumen be not more than the average, but afterwards the fragments agglomerate, and form a hard compact body; when the per centage of bitumen is high, it fuses at once into a pasty mass, and during the application of the heat bubbles of gaseous matter escape, leaving ultimately a carbonaceous substance, in which all traces of the original are effaced. Ignited in air, it burns with a yellowish flame, which is intermittent, unless the fuel be kept repeatedly stirred, so as to prevent its caking. The latter tendency renders this coal unsuitable for many operations where great heat is required, as the draught is impeded by its caking properties. It is, however, a valuable fuel, especially

as it is very often possessed of qualities which render it applicable for the manufacture of gas and coke, the latter being most eligible as a heating agent where the coal itself cannot be employed.

Caking coal is very general, being met with in almost all the coal-fields of Great Britain, but more especially in the Newcastle and Wigan districts.

Splint or Hard Coal.—This variety occurs most abundantly in the Glasgow coal deposits, where, for general application, it is highly prized. Its color is black or brownish-black, and its lustre resinous and glistening. When broken, the principal fracture appears imperfect and slaty, but the transverse one shows it to be fine-grained, uneven, and splintery; hence, as well as from its hardness, the term *splint*. It kindles with greater difficulty than the preceding variety, but when once ignition has taken place, it produces a fine clear fire, and throws out much heat.

Cherry or Soft Coal.—The similarity in physical appearance between this and the caking coal is very great, though for the most part the lustre of cherry coal is much more splendid, and hence the name given it by the miners. It differs from caking coal in not undergoing fusion when heated. Owing to its great brittleness, it is not economical in the working. It readily ignites, and makes a lively fire, yielding a clear yellow flame, but is consumed rapidly. This species is likewise met with in the upper strata of the Glasgow beds, as also in Staffordshire, in the Lancashire district, *et cetera*.

Cannel, Candle, or Parrot Coal.—This variety has a very compact and even texture; a shining resinous lustre, and a color varying between a jet and a greyish or brownish black. The lustre of cannel coal is sometimes not so very distinct as that of *pitch coal*, which is a species of the caking kind; its compact texture and gravity are sufficiently characteristic to distinguish it from the other sorts. The fracture of cannel is flat, conchoidal in every direction, and sometimes slaty. It takes a good polish, and on this account is manufactured into numerous articles, such as inkstands, snuff-boxes, beads, *et cetera*.

Cannel is found in several coal basins, but most abundantly in the Wigan district, at Lesmahagow, near Glasgow, and at Coventry. It is so named from its property of burning and yielding a bright flame like a candle. The other name, *parrot coal*, which is of Scottish origin, is derived from its decrepitation when thrown on the fire, owing to pieces of the coal flying off when heated.

Many other local appellations are given to the coal even from the same field, if it includes many seams, but these are of little interest to the consumer.

Anthracite.—In speaking of the origin of coal, allusion has been made to this variety as being the oldest, and, consequently, the furthest removed from its vegetal source in composition and physical characters. This fossil, which is sometimes known as *glance* or *stone coal*, is a hard compact substance possessing much lustre, often iridescent; the more perfect variety is entirely free from bituminous matter, and hence it constitutes a class of the coal formation in itself. These characters are not observed in all the anthracites, which

generally retain more or less bituminous coal interstratified or otherwise mixed with portions reduced to the state of true anthracite. The mixed varieties, or semi-anthracites, admit of being employed as a substitute for caking coals in many cases where a true anthracite would not answer the purpose.

This is the densest of all the coals known, excepting such as are very earthy or otherwise mineralized. It contains, when a true anthracite, only carbon, water, and inorganic salts, but generally more or less hydrogen and oxygen, besides the proportion of the latter elements in the form of water. Anthracite is ignited with great difficulty, and being dense, and having a tendency to break up into fragments when heated, in consequence of the expulsion of the water contained in it, it is not calculated to produce a strong fire in the ordinary grate or furnace, although, when once thoroughly ignited, its calorific power is very great. By a suitable modification of the grate or furnace, and proper management, it may in numerous instances—not the least of which is its application to smelting—be employed with advantage.

Anthracite is found most extensively in America, where it constitutes immense deposits. In England, it is chiefly worked in the South Wales coal-field, although it may be met with in large quantities in other basins. The total area of this description of fuel in Great Britain and Ireland is about three thousand seven hundred and twenty acres.

CHEMICAL COMPOSITION OF COAL.—The localities and general characteristics of the principal varieties of coal having been noticed, the Editor will proceed to a more minute examination of its composition. It has been already laid down as a general principle, that the value of a fuel is proportional to the amount of carbon which it contains. Like other rules, however, this admits of exceptions, and, for some purposes, the coal is valued according to its per centage of hydrogen. This is especially the case with coal intended for gas manufacture, and also when employed as a fuel in such arts as require the heat to exert its power at some distance from the fire. Moreover, other ingredients may be contained in the coal in proportions very insignificant when compared with the carbon and other inflammable portion, but still so injurious in their effects as to render the fuel unadapted for many purposes to which it might otherwise be applied with good results. Among these are found sulphur, arsenical and other kinds of pyrites; and similar prejudicial effects are produced by the presence of considerable portions of sulphates, or, in fact, of any mineral matters which undergo no change during the combustion. The pyritous ingredients are, however, the most deleterious, as during combustion they evolve sulphurous acid, and if arsenic be contained in the coal—which is fortunately a rare occurrence—arsenious acid will be eliminated. Now, both the sulphurous and arsenious acids are highly obnoxious and dangerous, and ought to be avoided as much as possible. From all these considerations, it is evident that, to determine the quality of any species of coal, with a view to ascertain its fitness for a given purpose, nothing short of a knowledge of its ultimate composition can be relied on; and

From this table it may be seen that the specific gravity of coal ranges from 1.2 to 1.5, rarely exceeding the latter; and further, by rejecting those samples which yield very large per centages of ash, the mean gravity will be about 1.30. It will also be observed, that the relation existing between the mineral constituents of the coal and the density is quite irregular, and, consequently, offers no trustworthy grounds for inferring the per centage of ash which a coal may contain merely by determining the density, or inversely. It is true, however, that in numerous instances, samples with a larger proportion of ash will be found to have a higher density than those which contain less inorganic matter. This is more especially the case with different samples of coal from the same mine, which led JOHNSON to infer that the specific gravity and mineral constituents of the coal from the same bed have a constant relation to one another. The basis on which he erected this theory, is found in the following results of the analyses of four samples of coal from Beaver Creek, Lucerne County:—

No.	Specific gravity.	Per centage of ash.
1,	1.560	1.28
2,	1.594	4.00
3,	1.613	5.01
4,	1.630	5.063

The same increase was observed with four other

samples from the coal field of Maryland, bordering on Pennsylvania, thus:—

Mean specific gravity of two specimens.	Mean per centage of earthy matters in two specimens.
1.320	7.52
1.350	9.58
1.365	10.35
1.385	11.75
1.485	14.41

Admitting that a high density is to some extent an indication of the presence of mineral matters in greater abundance, yet it is impossible, even approximately, to estimate the per centage of these by this test, since no fixed and constant relation can be established between the two. Besides, it is well known that a great difference in the amount of mineral matters is sometimes detected in coal from the same working.

The nature of the inorganic matters in coal affects, in a great degree, not only the gravity of the substance, but its quality as a fuel, although the components found are generally the same in all. From the tables already given, it will be seen that the total quantity of ashes fluctuates between one and twenty-five per cent., the average being about ten per cent. or under. The following table of the analyses of the ashes of coal by PHILLIPS, shows the nature and extent of the components, which, strange to say, contain no alkalis:—

	NAME.	Silica.	Alumina and oxide of iron.	Lime.	Magnesia.	Sulphuric acid.	Phosphoric acid.	Total per centage.	Per centage of ash in coals.	Per centage of coke in coals.

Lead, copper, iron pyrites, and traces of iodine, *et cetera*, are also found in coal, but are by no means general. In fact, the traces of lead and copper are sometimes so minute as not to admit of estimation; but this is not the case with the iron pyrites. In some varieties this compound may be readily distinguished in clusters of cubic crystals, or in seams running through the mass; and, from its characteristic yellow appearance, the coals in which it is thus found are named *brassy coals*. It operates more injuriously than any of the other mineral compounds, as, during the combustion, the sulphur is transformed into sulphurous acid, which in itself is poisonous; and although it passes off considerably diluted by the other gases produced, yet it is hurtful, not only to animal life, but to many manufacturing processes, as well as to the boilers and furnaces of locomotives. When sulphurous coals are distilled, one-half or a certain portion of the sulphur is eliminated in the form of sulphide of hydrogen and sulphide of carbon, whilst the remainder is left united with the metallic base in the coke. In both cases it is the cause of much trouble and injury, as every gas manufacturer and smelter well knows. But these are not the only evils resulting from the iron pyrites. When coals containing it in large quantities are stored, and are affected with moisture, it not unfrequently happens that spontaneous ignition sets in, in consequence of the bisulphide being converted by

its oxidation into sulphate of iron, and generating at the same time as much caloric as determines the combustion of the carbonaceous matter, which ultimately may reach to a red heat. To guard against this danger, it is well to expose the heap as much as possible to a current of air, in order that the moisture may spontaneously pass off, and the entire mass be kept cool; or, if incipient combustion has already set in, it may be arrested by loosening and turning over the heap, so that the air may pass through it freely. This spontaneous combustion is more apt to take place in mines than in the coals even when stored, unless, indeed, they are accumulated in confined places where the temperature is somewhat elevated. Under such circumstances, aided by the presence of moisture, the coals are very liable to burn voluntarily. Although the combustion which has been going on in some mines for considerable periods, cannot be attributed to the oxidation of the pyrites, but rather to the large volumes of inflammable gases which are generated in crevices in the mass, and which are accidentally ignited, yet it cannot be doubted that, through the combined action of water and a limited supply of air, the mineral assists in developing the heat throughout. When a mine takes fire, it resists every effort to extinguish it, unless the whole working be so regulated as to admit of being flooded with water. This, however, is rarely the case, nor is it ever thought of as a provision for such an emergency; and yet it is the only effective precaution that can be adopted, for the numerous fissures in the coal, which often extend to the surface, serve the purpose of powerful chimneys, whilst other chinks co-operate with the shafts, in conveying air to the seat of the fire. Every exertion has been made to check the combustion going on in some of the British mines by the erection of dams; but, although it is believed that in some of them the rate of consumption is much reduced, it still continues.

Although the specific gravity of coals and the per centage of ash which they contain are very insufficient tests of their value as fuel, yet it is evidently important to know the amount of the combustible constituents

in different kinds. Fortunately, numerous analyses of coals have been made; and the Editor feels assured that a summary and compendious view of the most important of these cannot fail to be deeply interesting to all who are concerned in those arts and manufactures in which fuel is an object of primary considera-

tion, as well as to the scientific analyst. Accordingly, the following tables exhibit the results so elaborately worked out for the Admiralty by Dr. LYON PLAYFAIR, and others, in their examination of nearly all the products of the British coal mines:—

MEAN COMPOSITION OF AVERAGE SAMPLES OF WELSH COALS.

Having seen in the foregoing the ultimate constituents of the several varieties examined, and also the amount of coke which they afford when heated in close vessels, the next point that demands inquiry is the state or condition in which those elements are contained in the coal. It is the belief of many, that common coal is compounded of a carbonaceous substance like anthracite, and a bituminous one; and it would appear, from the microscopical researches which have been made, that such is usually the case. When, however, the fusibility of good coal is considered, and the homogeneous mass which it yields upon exposure to heat is closely examined, one is led to infer that the carbon is not isolated, but combined with the other constituents in such a manner as to form a definite body. Doubtless, in some species of lignite, the bituminous matter is partly distinct from the carbonaceous; this may be deduced from the considerable quantity of tar which they yield, and the friable porous nature of their coke. From many facts connected with the manufacture of gas and other products from coal, it must be evident that this substance is chiefly composed of various carbides of hydrogen, which suffer decomposition by heat, and which, from the circumstance that suitable solvents have not yet been discovered, remain unisolated. It is an authenticated fact, that the more the amount of hydrogen in a coal exceeds that of the oxygen, the more fusible is the substance, and *vice versa*; but this surplus is not sufficient to account for its fusibility; the entire quantity is concerned in producing the effect. When the amount of hydrogen is small, the coal will not be so fusible as when the proportion is larger, although, in the first case, the ratio in which it stands to the oxygen may be much greater than in the second. If the absolute per centage of hydrogen is only about two, there is little reason to expect that such a coal will undergo fusion when submitted to heat. Experiments have shown that it requires at least three per cent. of hydrogen in

the substance, with as much oxygen as will combine with half of this to form water, to render it fusible under the influence of caloric. Such a coal affords a very intumescent coke. Coals less inclined to melt than one so constituted, may contain a variable amount of hydrogen; but when the proportion exceeds one-and-a-half per cent., the oxygen will be required in quantities capable of transforming at least two-thirds of this into water. On the other hand, if the hydrogen and oxygen be exactly so proportioned in the coal as to form water, the coal will be infusible, and the coke which is left will be pulverulent. It is remarkable that many substances constituted of carbon, hydrogen, and oxygen, differ in this particular from coals; thus sugar, gums, starch, when submitted to heat, fuse, and yield a compact coke. Hence it may be inferred that whether an organic matter containing about forty-eight per cent. of carbon, with oxygen and hydrogen to constitute water, shall be fusible or not depends on circumstances still requiring explanation. When the quantity of carbon exceeds fifty per cent., the substance is or is not fusible, according as the amount of hydrogen is or is not in excess above that which is necessary to convert the oxygen into water. All woody and fibrous matters are infusible, owing to their content of carbon being more than fifty per cent., whilst the oxygen and hydrogen making up the remainder are so proportioned as to compose water; there are, however, other bodies in which the carbon constitutes from half to nine-tenths of their weight, and yet they are fusible and even volatile under the influence of heat. Such is the case with some of the resins, wax, *et cetera*, which contain a large quantity of hydrogen that assimilates itself with the carbon, giving rise either to gaseous bodies, or liquids, into which the latter largely enters. It is upon these grounds also that the explanation of the fusion of coals so rich in carbon as eighty per cent. rests.

In many branches of trade, experience has pointed out the advantages which some varieties of coals afford,

from the circumstance that the nature of their combustion is adapted to the special work assigned them. Hence the selection of gas coal, steam coal, and such like, on account of the respective qualities they possess; the former of producing large quantities of gas, the latter of yielding a high temperature, at the same time that its combustion is tardy and gradual. The first are evidently such as, when heated, enter more into fusion, as is obvious from the adoption of cannel in gas-works whenever it can be found. For generating steam, coals which are only slightly fusible, and bordering upon the nature of anthracite, are found from experience to be the best. For various other manufacturing purposes, the particular requirements of each must decide the fittest quality of fuel. In reverberatory furnaces, and such others as are constructed with the view of producing an effect at a distance from the fire, flaming coals will be found best adapted for the purpose, but not those which are apt to form a coherent cake in the grate, whereby the draught would be impeded, and the combustion be inadequate to the effect required. On the other hand, where the heat must be very intense, those coals are found to be the best which contain a large percentage of carbon, with enough hydrogen and oxygen as will generate sufficient quantities of inflammable gases to promote its rapid ignition, but at the same time not so much as will effect fusion to any considerable extent. Such is the kind required in the smelting of metals, for the working of iron, *et cetera*. This subject will be further explained when the values of fuel come under consideration.

Torbanehill, or Boghead Coal.—The peculiar characters of this substance, on the nature of which geologists and chemists were much divided, attracted very great attention several years ago, and led to important legal proceedings, arising out of the following circumstances. In the beginning of the year 1850, a contract of lease was entered into between the proprietor of the estate of Torbanehill, near Bathgate, Linlithgowshire, and the Messrs. RUSSEL, Falkirk, conveying to the latter, in consideration of a fixed rent, a right to the whole coal, ironstone, iron ore, limestone, and fire-clay, on the lands of Torbanehill, for a period of twenty-five years; but the lease was not to comprehend copper, or *any other mineral whatever except those above specified*. In the course of their researches, the Messrs. RUSSEL had previously found an extensive deposit of the Torbanehill coal, which was shown by Dr. PENNY, in 1849, to be invaluable as a coal for the manufacture of gas. As such, it was worked and disposed of by the Messrs. RUSSEL, to whom, at the very small rent at which their right to the minerals was acceded, it promised to be a source of large revenue. In these circumstances, the proprietor of Torbanehill brought an action against the lessees for damages, laid at £10,000, on the ground that the substance was not coal at all, nor any of the minerals comprehended in the lease, and that, therefore, the lessees had no right to remove it. The case was tried at Edinburgh, before the Lord Justice-General and a special Jury, in the months of July and August, 1853, and excited intense interest, both on account of the curious scientific question involved, and the number

of eminent professional authorities cited on both sides as witnesses. The apparently conflicting character of their testimony was also somewhat remarkable. Professor ANSTED, for instance, did not give the substance any name at all; Professor BRANDE said it was a new peculiar mineral; Professor CHAPMAN had no hesitation in pronouncing it a bituminous shale; the late Mr. HUGH MILLER characterized it as the most inflammable shale he had ever seen. Dr. THOMAS ANDERSON said it was not a bituminous shale, whatever it was. Dr. WILSON said he would call it a clay impregnated with bituminous matter, and Mr. MILNE, in like manner, called it a clay bituminated. On the other hand, Dr. FLEMING of Edinburgh, Professor GRAHAM, Dr. JOHN STENHOUSE, Professor JOHNSTON, Dr. PENNY, Dr. HOFMANN, Dr. FRANKLAND, and other equally eminent authorities, pronounced it unquestionably a coal. At the same time, the only material difference, with reference to the facts of the case, appeared in the results of the microscopical examination. The geologists and chemists agreed as to the constitution of the substance—they differed only in the name which they were inclined to give it, according to their special views of what constituted coal; but not so the microscopists, three of whom were examined for the plaintiff, and four for the defendants. Of these gentlemen, the former agreed in asserting that there was no trace of organic structure, no woody fibre or tissue—in short, no trace of vegetal matter in the substance under consideration; on the other hand, the defendants' witnesses affirmed that in every part of it there was the clearest evidence of vegetal structure; and three of these gentlemen were skilful botanists, whilst those examined for the plaintiff did not lay claim to that character. Even the microscopical evidence, therefore, was strongly in favor of the claim of the Torbanehill mineral to be considered a true coal; and this, in concurrence with the general analogies presented, induced the jury to return a verdict for the defendants. In this verdict—which quite harmonized with the opinion pronounced by Dr. PENNY before the Torbanehill coal became a subject of litigation at all—there seems to be no difficulty in acquiescing. Among the recognized true coals, there are infinite diversities in the relative proportion of the ingredients—from anthracite at one end of the scale, to cannel or parrot coal at the other; and the Torbanehill coal appears, from its composition, to be not less justly entitled to the name of a coal than anthracite, though standing at the opposite end of the scale.

In all its leading physical and chemical characters, it is identical with other varieties of cannel coal. It is unquestionably of vegetal origin. It forms a seam varying in thickness from sixteen to twenty-one inches. Its geological position does not differ from that of other Scotch cannel coals, and the associated rocks are similar to those that occur in other coal fields. In the upper part of the seam the color of this coal is brown, and the streak light yellowish-brown; but in the lower part its color is black. Fossil plants, especially stigmaria of various sizes, and with numerous rootlets, are found in every part of the coal. Some are in the shape of large trunks of trees, one or two feet in diameter. The impressions of scalariform

vegetal tissue are also exhibited in almost every fractured surface. The following section of the cannel coal-fields of Scotland, by Mr. JOHN GEDDES of Edinburgh, shows the relative position of the coal, and its depth in fathoms from the surface:—

Caplekrae. Muirkirk. Lesmahago. Inzievar and Tory. Wemyss and Methill. Torbanehill.

s. Limestone.
t. Various strata.

The color of this coal varies from dark snuff-brown to dull brownish-black; streak light brown; powder dull olive brown-black. It does not soil the fingers; it adheres to the tongue, and it has, when moistened, the odor of clay. It is exceedingly hard, and very difficult to break in a direction perpendicular to the plane of stratification. It is distinctly laminated, and the large rhomboidal blocks, as brought from the pit's mouth, may be readily split into thin slabs, less than an inch in thickness. Its fracture is slaty, and often beautifully conchoidal. When struck with a hammer, it gives a distinct and deep woody sound. Does not become electrical by friction. Specific gravity varies from 1.155 to 1.260; average about 1.1892.

Its microscopical characters have been ably discussed by Professor REDFERN, in the third volume of the *Quarterly Journal of the Microscopical Society*.

It readily ignites, and burns with a bright, voluminous, and smoky flame. In the open fire it splits, and crackles like other cannel coals. It does not intumesce or melt. When completely burned, it leaves a considerable quantity of fine white ash, amounting on the average to twenty-one per cent. Several cannel coals give a larger quantity of ash—page 85. The ash contains, in 100 parts:—Silica, 56.0; alumina, 43.52; oxide of iron, 0.35; potassa, 0.4; soda, 0.36; with traces of lime, magnesia, phosphoric acid, chlorine, and sulphuric acid. HERAPATH has proposed to use the ash in the manufacture of alum. This coal is not appreciably acted upon by ether, bisulphide of carbon, benzol, oil of turpentine, or naphtha. When distilled in the usual manner, it gives the same products as other cannel coals—namely, gaseous hydrocarbons, tar, paraffin, paraffin-oil, naphtha, naphthalin, benzol, ammonia, *et cetera*.

It contains every ingredient found in other varieties of coal; and there is no substance in it that does not exist in other coals. The results of its elementary analysis by Dr. PENNY, after being dried at 212°, are shown in the following statement:—

	With ash.	Without ash.
Carbon,	63.936	81.159
Hydrogen,	8.858	11.245
Nitrogen,	0.962	1.221
Sulphur,	0.320	0.406
Oxygen,	4.702	5.969
Ash,	21.222	—
	100.000	100.000

It yields about 67.0 per cent. of volatile matter, and 31.7 of coke. Different specimens, however, vary considerably in this respect, as shown in the following table, which exhibits the results of the analysis of four specimens taken from the pit at different dates:—

	Brown.		Black.	
	1849.	1851.	1851.	1853.
Volatile matters, ...	71.0	71.0	62.70	67.11
Fixed carbon, ...	11.3	7.1	9.25	10.52
Ash,	16.8	21.2	26.50	21.0
Sulphur,	0.3	0.2	0.35	0.32
Water,	0.6	0.5	1.20	1.05
	100.0	100.0	100.00	100.00

Coke,

Specific gravity, ... 1.1550.. 1.160.. 1.2185.. 1.1882

In its chemical composition this coal is characterised by containing more hydrogen than any other variety, and by giving less fixed carbon and more ash than most other coals. Its coke, which is valueless as fuel, contains 33·4 per cent. of carbon and hydrogen, and 66·6 per cent. of ash. It surpasses all other cannel coals in its gas-producing powers. It yields from thirteen thousand to fifteen thousand cubic feet per ton, whereas the best qualities of other coals give from eleven thousand to twelve thousand cubic feet. The gas produced from

it is extremely rich in hydrocarbons, which burn with flame possessing a high degree of luminosity; hence this coal is admirably suited to be mixed with inferior varieties of cannel coal in the manufacture of gas. When distilled at comparatively low temperatures, it affords large quantities of paraffin, paraffin-oil, *et cetera*, a discovery made and patented a few years ago by Mr. YOUNG. Several interesting products have recently been obtained from it by GREVILLE WILLIAMS.

The following table will be found useful:—

MEAN COMPOSITION OF VARIOUS SCOTCH CANNEL COALS, ANALYSED BY DR. PENNY OF GLASGOW.

* Not estimated.

COKE.—Like wood and peat, coal has been found unadapted for many purposes in its natural state; either the heat which it evolves is insufficient from the presence of water and other ingredients, or the same effect is produced by the tendency of most coals to fuse and form a coherent mass, whereby the air is excluded, and the combustion impeded. Although the latter is the most frequent cause of failure, both contribute to render coals inapplicable to the wants of many of the arts and manufactures. To obviate these difficulties, and to bring the coal to a state in which it will yield the greatest possible amount of heat, recourse has been had to carbonization, the idea being borrowed, doubtless, from the advantage gained by a similar treatment of wood. By this operation, the principles of which have been already explained, the volatile products are expelled, and the liquid bodies decomposed, so that their carbon becomes to a great extent fixed, whilst the hydrogen and oxygen are dispersed. These volatile matters are utilized or not, according to the circumstances and the locality in which the carbonization is carried on. Thus, when the operation is conducted in large towns, the gases become not only a source of profit to the persons engaged in the trade, but of comfort and safety to society by their illuminating power. In

localities which are not populous, or which are far removed from cities and towns, these valuable products are permitted to pass off, not only uselessly, but often injuriously to animal and vegetal life. In either case, the fixed matter left is known as coal-charcoal or coke.

The charring of coals is conducted under these circumstances with very different objects. In towns, the coke is, in fact, only a secondary product, and is little regarded in comparison to the volatile matters, whilst in those places where the coal is burned on the field for the smelters and for locomotive purposes, all the value is attached to the solid body remaining. These latter—the iron trade and steam locomotion—are the principal sources of consumption of this kind of fuel; and since the introduction of both upon an extended scale, the inventive genius of scientific men has been exercised to discover methods of carbonizing the coal, not only more rapid in action, but also more effective, and calculated to produce a substance as much as possible divested of the volatile bodies which diminish its heating power. It could scarcely be expected that a subject so interesting as this, so important to many branches of manufacturing industry, and consequently so well meriting the attention of intelligent

scientific and practical men, could long rest without eliciting many suggestions towards improvement. How far these have been attended with success, will appear in the following pages.

Adopting the same arrangement as in former cases, it may be well to say a few words, in the first place, on the charring or coking properties of *brown coal*, which is sometimes employed for this purpose. In Great Britain, where bituminous and stone coal abound to the extent already stated, and where the presence of lignite is very partial, the latter is carbonized with the view of rendering it more useful—a practice, however, restricted to those places where the more perfect coal is scarce. Where such conditions exist, the charring of lignite—a work which is difficult and troublesome to effect—is repaid with very indifferent results. This arises from its peculiar property of splitting asunder as the heat enters, and hence the mass when charred is little else than a heap of small fragments which are unsuited for those works requiring the use of a compact coke. It is stated by ROSCHERS, that lignite, if thoroughly dried in the air immediately after it is taken from the pit, and then slowly charred, affords a charcoal possessing considerable cohesive properties; and MAYER, in like manner, affirms that the inconvenience may be obviated by subjecting the coal to slow carbonization after it is taken from the mine. The methods usually adopted are similar to those already described for the charring of wood and peat; but the yield from this species of coal is so small, that the labor bestowed upon the operation is hardly repaid. In the German works, where lignites have been charred, the per centage of charcoal by weight averaged from fifteen to eighteen per cent., and by volume from about thirty-two to thirty-five; but this quantity is much below that obtained on a small scale, when the carbonizers used are close crucibles.

The annexed table gives a synopsis of the per centage which various lignites afforded by this treatment:—

Bohemia.

The carbonization of lignite is a subject of but little interest to manufacturers, in consequence of its use being so very limited. The Editor will, therefore, proceed to the consideration of pit charcoal, which is of vast importance to every country aspiring to progress in civilization and manufacturing industry. More particularly is this the case as regards Great Britain; for the extent of her smelting establishments, and her vast application of steam power in locomotion, as well as in various manufactures, call forth every exertion to supply the most perfect source of heat which skill and science can provide. Not only do her own industrial wants demand this, but other countries, which are not so highly favored in the amount of fossil fuel at their command, make urgent calls upon her resources; and coals and coke are exported to a considerable extent to supply the railways and steam navigation of other states.

The extensive variety of coal met with necessarily suggests a corresponding difference in the effects produced by the action of heat upon them, and it is to be expected that the products should indicate similar differences. All coals which are in any degree bituminous, yield three classes of bodies—namely, the residuary matter, containing carbon in excess; the liquid substances, which are in like manner very carbonaceous; and the gaseous bodies, of which there are several. It is almost needless to remark, that the proportion of the second class will be dependent upon the fusibility of the coals; and even the third is chiefly derived from fusible or caking coals. As a general example of the nature and relative proportions of these three varieties of products, the following analysis may be taken:—

	Centesimally.
Coke,	68.925
Liquid products. { Tar,	12.230
“ { Water,	7.569
“ { Light carbide of hydrogen,	7.021
“ { Carbonic oxide,	1.135
“ { Carbonic acid,	1.073
Gaseous products. { Olefiant gas,	0.753
“ { Sulphide of hydrogen,	0.549
“ { Hydrogen,	0.499
“ { Ammonia,	0.211
“ { Nitrogen,	0.035

While the absolute and relative yield of these products depends chiefly on the composition of the coal, the method and management of the operation to which they are submitted exercises a marked influence. Thus it may be seen practically that the products differ to the extent of several units per cent., according as the heat applied in the charring is low and gradual, or elevated and rapid. In the amount of coke, which constitutes by much the largest product, or more correctly, the residue, the observed variation from this cause is sometimes so high as six per cent., but generally it ranges from three to four per cent. It is not only in quantity, however, that the mode in which the heat is applied produces a marked effect, the quality is liable to not less variation from the same cause. By the application of a low prolonged heat, gradually raised till it reaches the strongest red heat towards the completion of the carbonization, the coke is more compact, from the circumstance that the fusion of the coal is more perfect under the gradually increasing temperature, than if the latter were applied suddenly in full force. As a general rule, these matters are little attended to in the British coke districts, the coal employed being so bituminous as to yield, under either of the conditions above stated, a compact mass, which can endure the effects of carriage, *et cetera*, without sustaining much injury.

The several methods in use for the charring of coal, for whatever purpose, may be comprehended under three heads: namely, distillation in close vessels; heating in open heaps; and a method in which the principle of both is to a certain extent brought into requisition.

Of the first mode it is sufficient to say, in addition to what has been already stated, that the coke so produced is not only limited in amount, but is of such a nature as to render it inefficient where a very compact dense fuel is required, as in the iron furnaces and the like. Indeed, when close distillation is resorted to, the coke is less an object of consideration than the liquid and volatile products; and, therefore, it will be more in keeping with the Editor's plan to speak of it hereafter under the article GAS. By the second method, the advantage is gained of preparing a large quantity of the fuel in a short time; but at the loss of considerable quantities of material, as will be seen afterwards. The third method in which a furnace of a special form is employed, and which admits of operating upon a large quantity of coals at once, is that which is daily becoming recognised as the most economical, for it operates quicker, with less loss, and requires less attention than the others.

Coking by the second method, or the open heap, requires nearly the same operations as the carbonization of wood, only that the mounds are not so large, and they require less attention. Two systems are followed, the one characterized by the round heap or pile process, and the other by the coals being arranged in rows or ridges. For the purpose of coking in heaps, a level plot of ground is selected, the area of the heap marked out, and the coals piled upon it, placing the larger pieces at the base, and so on to the top. Fire is then applied in a cavity of about a foot in diameter, which is formed in the top for this purpose, and the

carbonization allowed to proceed. In a short time the entire mass is covered with the fire, owing to the combustible gases which are discharged, and which, igniting, conduct the fire over the whole of the coals, at the same time that they prevent its loss by shielding the heated solid carbonaceous matters from contact with oxygen. When the whole mass is at a red heat, or nearly so, and the dense heavy smoke which is emitted as long as the decomposition of the volatile ingredients in the fuel is actively proceeding has ceased, a light coating of coke ashes, or the rubbish which has accumulated, is thrown on, and the air entirely excluded. Sometimes the mound is covered with straw, dried leaves, or brambles, and coke dust or clay, before it is ignited; but this is not generally thought necessary, as the density of the coal and the downward progress of the fire, till it reaches the base of the heap, are sufficient protection against any greater loss than that which it would sustain even when covered. The period of charring a heap of twelve to sixteen feet in diameter, and two and a half to three in height, extends over two or three days before the work is finished. WILKINSON'S modification of the process, by the construction of a chimney in the middle of the meiler, so that it may serve as a draught to any portion of the mass, has been productive of great advantages in coke-making, and has, with slight modifications, been adopted in Staffordshire, on the Clyde, in Scotland, and at several other places. This appendage to the meiler is usually of a conical form, the base being about three feet in diameter, and from one foot and a half to two feet at the top. The bricks are laid so that intermediate channels present themselves all round the pile. At the top it is solid, and closed with a lid. Its height is usually three or four feet. Around the base of this chimney the coals are piled, employing the larger pieces for the base, and putting the smaller ones on towards the top and outer surface. Several channels are fashioned in the mass from the base of the chimney to the outside of the heap, through which a supply of air traverses to the region of combustion. The preliminaries being effected, and the heap coated with powdered coke or rubbish, fire is introduced at the mouth of the chimney, either by means of ignited coals or wood. The calorific which is evolved laterally through the openings in the chimney, very soon ignites the coal adjoining, and the heat extends gradually outwards to the circumference as the charring advances. As soon as the thick heavy smoke from the chimney is replaced by a lambent blue flame, it is significant that the fire has traversed the entire mass. It is now watched till the azure flame abates, at which time the draught of the chimney is cut off, by depressing the cover, and filling any chinks or cracks in the coating with fresh material. After the lapse of a few days, the process is finished, and the coke is ready for drawing. Fig. 57 represents an elevated section of this mode of charring, showing the chimney and the draught holes opening in all its circumference, and thus offering a flue for the volatile products to pass away. Sometimes this kind of meiler is ignited at several parts at the outside, near the channel flues at the base. In a short time the fire will reach almost to the centre. A few air or vent holes may now

be made in the covering, by thrusting an iron bar into the heap. The smoke and other volatile compounds issue

Fig. 57.

partly by these, but care must be taken to frequently renew the perforations, as, when the coals are very bituminous, the fusion of the mass is apt to choke them up. In about twelve hours or less after ignition, the fire will have spread over the whole heap, which may then be loosely covered with coke refuse, ashes, *et cetera*, leaving the vent or chimney still free. During two or three days the smouldering proceeds, by which the volatile portions suffer distillation, and are emitted by the orifice last mentioned, and the cooling will have advanced so far as to allow of the coke being used. By this mode of permitting the whole heap to get ignited before covering, and subsequently leaving the chimney open, the elevated temperature is retained sufficiently to carbonize the mass, and at the same time a waste of coke is avoided; moreover, another important advantage is gained in the expulsion of much more sulphur than could be effected if the air were more freely admitted during the operation.

It deserves also to be mentioned, that the coke manufacturer, by constructing the meiler upon a moist ground, effects a purification from the sulphur by means of the vapors arising from the soil, and passing through the red-hot mass. In this case the water must suffer decomposition, its oxygen passing over to the sulphur, so as to form sulphurous acid, and the hydrogen constituting, with the carbon, light carbide of hydrogen, thus :—

When the sulphur is united to a metal, and the aqueous vapor transmitted over it, the following changes are more prevalent, assuming M to represent the metal in combination :—

If, however, the heat be too great, or more air than is requisite be permitted to pass through the mass, this decomposition will not take place, and the sulphur in great part remains. The same end might be obtained by suffusing the ground with water before forming the heap.

It should be remembered, however, that in this case, as in the charring of wood, in proportion as watery vapor traverses the incandescent mass, so a loss of the carbonaceous substance is sustained. This will be evident from the above formulæ; but the importance of having the sulphur removed from the coke, especially when destined to be used in the smelting of iron,

is much more thought of than the advantage of obtaining a large product.

For the most part it happens that the circular mound, notwithstanding the assistance which the central chimney affords, is too massive and solid to allow the heat to operate with its fullest effect upon the coals. The want of this distribution of caloric is supposed to be the cause of the coke retaining more or less hydrogen and oxygen, which injure in some degree its value. To remedy this, the method of *coking in rows* is resorted to. A site is marked out, the extent of which depends upon the amount of coke which is to be prepared. A line is stretched along the length of the plane, in the middle of the space which the ridge is to occupy. At the distance of seven or eight feet apart, stakes, six to eight inches in diameter, are fixed in the ground. Large pieces of coal are then laid at each side of the string, and inclined to one another, so as to leave a channel in the midst. To insure greater strength to the walls, if the first rows may be so termed, the plane of cleavage of the coal should form a right angle with the length of the heap. Other layers of coal in proportion to the size are placed beside and upon the first two, using the largest coal first, till the row is sufficiently high and wide, taking care that air channels are left at intervals in the base. The usual height to which these ridges are raised is about three feet. When completed, the whole is covered with coal dust or cinders, and fire applied at several parts adjoining the air channels; the stakes are likewise drawn, and live coals thrown into the vacant space which they leave. In a short time the whole mass will be in a state of active combustion. As soon as the heat has penetrated to the centre, the pile may be covered more closely, leaving the portion left void by the stakes as free as possible, so as to perform the office of a chimney. In case these should get choked by the fusion of the coal, they must from time to time be cleared by thrusting a bar of iron into them, or into any parts where the combustion is dilatory. As soon as the white flame resulting from the combustion of the carbide of hydrogen disappears, and is succeeded by a lambent bluish blaze, all the orifices are closely covered, and the whole is left to cool.

Such is the simple mode of coking in heaps and rows, but it may be remarked that particular modifications are required according to the kind of coal which is to be carbonized. Thus, when there is a large portion of fusible matter in the coal, care must be taken that the draught holes or flues are sufficiently wide to admit of the increased volume which it acquires by the effects of the heat upon it, without being closed thereby; the fire, also, must be allowed to spread over the whole heap, as well interiorly as exteriorly, before it is partially covered with the refuse matter. When, by a closing of the draught or flue holes, air is prevented from entering to the heart of the mass, considerable time may elapse, and much of the exterior may be consumed, before the interior portions are charred; and it not unfrequently happens that while the outside of a ridge is completely coked, the interior is left intact. As an auxiliary to the process, when very bituminous coals are operated upon, the fire should not be kindled in the chimneys or spaces left by

the stakes till the base be well ignited; the facility which these afford for the escape of the products of combustion will expedite the process, and the result will be the general charring of the heap, whereas, if these precautions were not taken, the work would be but partially performed. The same observations will apply when the coal is small, and, therefore, forms a ridge which is less impervious to air. In the latter case, instead of stakes being driven into the centre, brick chimneys are erected, as in the meiler system.

Where there is great demand for coke, and the area admits of the construction of a large heap, one portion may be undergoing carbonization, whilst the other is being constructed, and thus the process of coking may be rendered continuous. The method of charring in ridges is preferred in most establishments where furnaces are not erected, as it affords a better coke, and is more expeditious than the other method. Among the more recognised benefits are the partial purification from sulphur, which arises, as has been stated, from the fact that the steam which evaporates from the base of the heap passes over the coke whilst at a red heat, and operates as already mentioned; hence, to insure this, it is customary, wherever practicable, to cut a dyke around the carbonizing plot, the water from which keeps the ground always damp. Besides the advantages which accrue from the floor of the heap being moist, the water is always required to arrest the too rapid combustion which is apt to take place in some parts of the ridge, and also to extinguish the incandescent charcoal when it cannot be allowed to cool spontaneously.

A modification of this method of coking has been followed for some time at the Janon Works, near Saint Etienne, in France, and is useful for economising the rubbish, slack, or small coal which could not be worked in the manner detailed. It is evident that the

adoption of some similar plan at many of the British collieries, where considerable quantities of coal of average quality are allowed to go to waste, would be highly advantageous.

The heaps or ridges which are constructed at the establishment alluded to, are almost of the same dimensions as those formed with large coal, and, like the last mentioned, may be either of an oblong or conical form, according as the ground affords the necessary facilities. To construct an oblong ridge, a board, *a*—Fig. 58—is placed in an inclined position, suited to that of the heap, and resting on two iron levers sunk in the ground. Against this are fixed other boards, *b b b*, one over another, and secured by

levers or bars of iron sunk in the ground at regular distances apart, and iron hooks. After the sides are ten or twelve feet in length, the prism is provisionally closed by a board, *c*, similar to

Fig. 58.

the first. All these boards are perforated, in order that conical stakes may be introduced to the interior through them, for the purpose of yielding ingress to the air in the spaces which are left after the latter are removed.

The arrangement of the lower conical stakes, by which these internal air spaces are formed, is seen in the annexed Fig. 59, where the stakes are represented in the position they would occupy when passing through the lowermost series of holes, *d d d*, in the walls of the ridge. A large stake, running longitudinally in the middle of the prism, forms the principal one. Upon this other smaller ones are fixed, as at *eee*, perpendicular to it. These being adjusted, or in readiness, a layer of the small coal, moistened to give it consistency, is thrown in till it rises to the level of the central stake, when the vertical ones are arranged as already stated, and a fresh quantity of coals added. By means of a heavy beater, the mass is rendered as compact as possible. A fresh layer of the slack is added, and beaten down as before, till the mass rises to the level of the second range of holes in the side boards, when horizontal stakes are laid from them, so as to abut against the vertical ones at a slight inclination. After the coal has been arranged

Fig. 59.

the third level, another series of rollers is laid down as before, only that it is not requisite they should be set obliquely. All these posts are generally three or four inches in diameter, and have a ring in the outer end to facilitate the drawing after the heap is formed. At this period the vertical stakes are drawn out, and then the side ones, beginning with those uppermost, and proceeding to the lowest. When this is done, the boards forming the walls are taken down and laid in continuation of the ridge, and the same order and operations are followed. In this way the prism is extended to any required length, but usually it terminates when it reaches from fifty to sixty feet in length, or even less than this, according to circumstances.

Ignition is commenced by lighting some round coal, placed at set distances in the upper holes, as well as in the middle of the heap. Care should be observed that sufficient space is left for the air to traverse these channels. In a short time the fire gains sufficient strength to ignite the whole heap gradually. As this is being attained, attention must be directed to the openings, that they do not become closed through the swelling of the mass, and, likewise, that cracks or fissures forming in the exterior are immediately closed with refuse coal. After the whole mass has become incandescent, and the evolution of whitish flame has ceased, water is poured into the lower longitudinal tunnel. By the conversion of this fluid into steam, and its passage through the mass, a further quantity of hydrogen and oxygen is expelled, as well as some

sulphur. When this operation is performed, the fire is extinguished by suffocation in the usual way. From six to ten days are required to complete the operation, and the coals afford half their weight of coke of fair average quality. It is evident that only caking coals are capable of being charred in this manner, as the non-bituminous varieties would not remain compact enough during the period of the firing.

The only drawback to this method, is the considerable consumption of coals which is necessary to ignite the mass, and which amounts to one-twentieth of the whole. By constructing the heap of a conical form, this may be reduced by one-half. It is done by an arrangement of boards, secured as in the prismatic heap, presenting the form of Fig. 60, and including a space of ten or twelve feet in diameter. A square stake, *a*—Fig. 61—is fixed in the centre of the pile, against which lean six conical stakes, *b b b*, placed at equal distances. The latter are perforated in the sides and upper part, for the purpose of receiving other stakes, *c c c*, which assume a vertical and horizontal position to each of the six principal ones. Coal is thrown in, and well rammed down, till it rises about three inches above them, when another series of stakes is laid down similar to the foregoing, only that the smaller stakes leading from the six larger ones are not directed above the preceding, as may be seen from the position of the holes in the larger ones. Another layer of coals is then laid on, and this course is pursued till the pile has risen to a height of three feet and a half, with a diameter of seven at the top. A number of smaller chimneys is

Fig. 60.

Fig. 61.

constructed by fixing, in the first series of stakes, vertical ones at the points, *m m m*, which rise higher than the top of the pile. In the subsequent details of pulling out the stakes and igniting the heap, no material difference exists between the method already described and that under consideration; the particulars of the carbonization are likewise the same in each. In this way much of the fuel which would otherwise be unsuited to such work as the smelting of metals, or for railways, is made to answer the same purposes as the best coal, and at little expense.

Another system to which the coke manufacturer has recourse, is that of heating in ovens. In this case the heat employed for effecting the carbonization is generated within the oven or furnace, and at the expense of a portion of the fuel. Were this not so, the product would be wanting in the necessary density and compactness for the iron furnaces, and, like the coke from the gas-works, would not be adapted for generating

high degrees of temperature. The method of coking in ovens is practised also for economy, as not only yielding a larger product of coke, but affording the means of recovering some of the products of the distillation. It is not, indeed, without its inconveniences, more especially if the coals be very much charged with sulphur; for, in this case, the coke retains that injurious element in much larger quantities than if the carbonization were effected in the open meiler. The ovens, however, can hardly be excelled for the production of a hard dense coke; and hence they are employed by several iron-smelters, especially those upon the Tyne.

The commoner arrangement for the coking of coals in this manner, is seen in the annexed engravings—Figs. 62 and 63—the first of which shows an elevation, partly

Fig. 62.

in section, of a series of four ovens constructed in a line, for the purpose of economising the heat; and the other a plan. They have a square or oblong form, with an area of twelve feet by ten, or less, according to circumstances. The height of the furnace is also variable, differing from three to ten feet. Sometimes about twelve hundred cubic feet of coal are charred in each at once. The walls of this construction, including the fireproof facing, are about two feet thick. In the arch is an opening, *a*, two feet in diameter, through which the gases and other products of combustion pass off. No grating is supplied in this case, the air being admitted through a perforated door, *b b b*, about three feet square, in the front near the base. This door is sometimes constructed of a stout perforated cast-iron plate; sometimes it consists of a mere frame, *d*, within which bricks are laid at such distances as will leave sufficient space for the admission of air. It is movable in grooves, *c c*, by means of a main, *z*, attached to a counterpoised lever. The coals are introduced through this as well as by the superior orifice; but it is stated, that when the charge is supplied from the top, the coke is not so good as when it is deposited in the furnace through the front door. It appears difficult to assign any

Fig. 63.

cause for this, other than that, when the filling takes place from above, the central part becomes so compact as to obstruct the free passage of air through it. Before charging, if the interior be not sufficiently hot, some wood is ignited inside the front door, and

allowed to burn, and, at the first charges, the combustion is assisted by throwing powdered sulphur upon the mass. During the evolution of dense volumes of smoke, the top door is left open, and also the apertures in the door at the base; as soon as these disappear, however, both are closed, and the contents are allowed to cool. After twelve hours, or longer according to circumstances, the solid mass of coke is broken, drawn out with rakes, and wheeled off in iron barrows to a receptacle where it is cooled by sprinkling it with water. After a furnace is lighted, the first and second batch of coke which it yields is very much inferior to what is produced when it has been in operation regularly for some time; this arises from the circumstance of the base and appendages not being sufficiently heated. After a few charges have been carbonized, and the masonry has become heated, the coke has not the sponginess which characterizes the first charges; the time occupied is also shorter, and there is no occasion for adding any fire, as the heat of the base and side walls is sufficient to ignite the coal in contact with them.

An improved form of this kind of coking oven is used in the neighborhood of Pittsburg in America. This is represented in elevation and section in Fig. 64. For the most part it is constructed of bricks, and on the side of an incline, affording a facility for unloading

Fig. 64.

the coal on the top of the oven, and therefore erected in a position accessible by rail or common road. The hearth is oval, this form being preferred in order to avoid the inconvenience arising from the adhering of the coke to the angular parts; its area is about the same as the English ones, but the depth is only about three feet and a half, instead of being ten, as in the preceding case. In all the other details, the two methods are similar.

In many parts of Germany and France, some of the products of the distillation are recovered, more especially the tar. This economy is not so much practised in the *coking* establishments of England, although her maritime wants require considerable quantities of this substance. The kind of furnace or oven constructed for the charring of coal and the collection of coal-tar in Silesia, is represented in section in Fig. 65. The oven is of a cylindrical form, eight to nine feet in height, and four in diameter. Any ordinary building materials are employed in constructing the exterior portion of this oven, but the interior must be composed of very refractory clay or fire-bricks. There are two principal openings, A and B, through which the coal forming the charge is introduced: the aperture, B, is closed by nicely fitting cast-iron lids, c, whilst the former may be secured by bricks and mortar, to which

security is given by a cast-iron plate. In the bed and wall of the oven metallic pipes are laid at intervals,

Fig. 65.

and encased with the masonry and brickwork; these serve to conduct air into the furnace for the purpose of carrying on the combustion to such an extent as will be sufficient to char the mass contained in it. They are seen at *a* in the base, and at *b b b* in the wall. All the volatile matters evolved during the carbonization are carried off through the cast-iron pipe, *D*, to a receiver, wherein the condensable portions are retained. In warm weather, and when work is active, this pipe is immersed in a water tank, intermediate, for the more effectually condensing the tar; but this is not required in the colder seasons. Care must be exercised in filling the oven, to deposit the larger coal upon the hearth, and so on, reserving the smaller for the upper layers. Inside the door, *A*, a space is left for the introduction of lighted coals or wood; but as soon as the coals have taken fire, the top door as well as the lower one are closed tightly, currents of air being circulated in the interior, through the openings in the wall and base of the oven. The upper rows of holes are closed also, the draught being instituted through the lower series, till such time as the contents of the oven have, at this level, reached a red heat. When this occurs, the orifices in the first row are closed, and those of the next opened, and left so till the fuel seen through them has assumed a red heat, after which they are closed like the foregoing, and the next opened. This process of opening the draught-holes is repeated till the whole of the charge becomes ignited. The time for changing the draught becomes pretty definite when the oven is regularly worked; thus, the coals will appear to glow, when viewed through the lower holes, in ten hours after lighting the fire, and this indicates the fit time for closing them; in about the same period, the second row may be secured in like manner; the third series remains open during sixteen hours, and the fourth only three hours. A period of twelve hours is then allowed for the furnace to cool, at the end of which time the coke is drawn. In this furnace the coals operated upon are slightly bituminous; they afford on an average about seventy-four parts by volume, and fifty-three per cent. by weight, of coke, together with rather more than five gallons of tar. The coke which is thus manufactured is very superior, in every particular, to that which

is prepared in the meiler, but the course of operations is, on the other hand, expensive and slow.

In the same locality, a mode is followed for economizing the slack and other small coal, by converting it into coke; and this course of procedure is not very unlike that described for the coking of small coal by the meiler system. The furnace is an oblong rectangle, with doors at each end, through which the small coals are wheeled in, and there, after moistening them with water to make them cohere, they are well beaten down. In the walls a number of air-channels are constructed, leading into the carbonizing space, and pieces of wood are laid between them, extending the whole breadth of the furnace. More coal is piled upon these, and pressed as solidly as possible till it rises as high as the wall, when it is covered with a thick layer of ashes and refuse matter. Some of these ovens are capable of charring from two to three hundred tons of coal, being about eight feet wide, five in height, and from forty to sixty feet in length. Fire is applied to the logs of wood, which have a diameter of four to six inches, and as these are consumed, they develop as much heat as serves to ignite the coal, and the space which they leave acts as a flue by which air is admitted, and the combustion extended to the whole mass. It is said that the loss sustained by the coal subjected to this mode of operation does not exceed twenty per cent.

In the vicinity of St. Etienne, and other localities in France, a coke oven is in use similar to what is represented by Fig. 66 annexed. In appearance it

Fig. 66.

resembles an ordinary baker's oven, with a low arched roof, and a flat hearth without a grate. The bed, *c c*, of the oven, which is nearly twelve feet wide, and twenty-three feet in length, is composed of a layer of refractory clay, well beaten down, and resting upon a base of cinders or other rubbish, *d d*, rendered as compact as possible. At each end of this oven there is a working door, *A A*, two feet nine inches in width and two feet in height, surrounded by a framework of cast-iron fixed in the wall, and in which a small sliding-door, *E*, moves; there are likewise apertures, *F*, for affording a view into the interior of the oven; and in the centre of the arch, a space, *B*, about eighteen inches in diameter, is left to serve for a chimney. The height of the oven, from the hearth to the most elevated portion of the arch, is four feet. Above the arch, which, like the hearth, should be composed of refractory material, common stone, mixed with sand and mortar, serves to give the whole solidity, and to retain the heat. The charge is lighted by first heating the interior with wood, but after a few charges have been drawn, the walls and hearth are sufficiently hot to cause the combustion of the coal. The depth of coal spread upon

the hearth should not exceed eight inches if it be of a caking nature; but when it has little of this property, the layer may be ten inches. A little water is sprinkled on the mass to promote its caking, and the whole is rendered as compact as possible. As soon as the layer is uniformly spread, the doors are drawn down nearly to the bottom, leaving a few inches free, however, for the admission of air. At first, aqueous vapor is given off, followed by sulphurous acid and the other products of combustion; but it is found advisable to suppress the rapid evolution of the latter, and to allow the slow expulsion of all moisture, at such a temperature as will be conducive, in the presence of steam, to dehydrate the coke from sulphur. All these products pass off by the chimney in the roof. When the whole of the moisture has been expelled, the disengagement of the combustible gases becomes more voluminous, and the gases themselves more inflammable; they ignite, and a smoke of a black color succeeds the dense yellow cloud which was given off during the emission of the watery vapors in conjunction with other bodies. When the black smoke appears, the draught is increased by raising the door to the height of three inches, in order to expel the whole of the volatile products. By this means the mass is in a short time raised to a cherry-red heat. After the lapse of from half an hour to an hour, the fuliginous cloud vanishes, and the gases emitted appear whitish. At this stage the heat will have spread over the whole mass, and a contraction in the bulk will have taken place, as may be judged from the appearance of numerous cracks and fissures in the red-hot mass. In about three quarters of an hour, these crevices will have penetrated to the hearth, and the entire contents will be at a full red heat. The doors are now tightly closed, as well as all the other apertures through which air might enter, and the contents of the furnace left to complete the carbonization. It is necessary to watch the operation, lest by the admission of the air through the chimney, which is the only opening left, a loss of coke might occur. After the doors are closed, the flame and smoke still pass off, but the latter by degrees becomes more attenuated and whiter, till it nearly ceases altogether; and as the pressure in the chimney is, at this period, considerably reduced, there is evident danger of a double current being established in it; namely, an outward current of the products of combustion, and an inward one of air. To guard against this, the mouth of the chimney is gradually contracted as the pressure of gases from within becomes less, till at their disappearance it is entirely closed. Attention must now be given to withdraw the coke in such a manner as to retain as much heat in the furnace as possible. To effect this, the doors are thrown open, and the mass of coke quickly broken up with long staves, then raked out, and conveyed away in barrows to a receptacle where it is sprinkled with water whilst red hot, both for the purpose of extinguishing the combustion and removing any excess of sulphur. Another charge is introduced as rapidly as possible, and after the preliminary operations already pointed out have been gone through, the doors are closed, and the charring is again managed in the same manner. Each charge is worked off in about twenty-four hours.

Figs. 67 and 68 represent a coking furnace in use in Belgium for carbonizing coal. In these figures, the

Fig. 67.

Fig. 68.

oven is represented at B B, the chimney in connection with this by A, and a flue leading to the latter by C C. The order of procedure is about the same in this as with the other kinds of ovens described, only that it contains a framework by which the whole of the charge may be drawn out at once when necessary.

In those ovens which work off only a thin stratum of coal, the coke which is formed is never so good as in those in which a thick bed is charred. It is more difficult, however, to carbonize the coal under the latter circumstances, and the product is less in amount. This arises from the fact, that when the mass is thick, and the coals are of a fusible nature, the air is prevented from passing up through the heap, and the result is a superior layer of coke, a middle band of charred material, and the lower layer of undecomposed coal. Even when the coal is not fusible, but contains considerable quantities of ashes, the effects are the same; for, under the influence of heat, the mass cracks into blocks of some dimensions, and the ashes which result from the entire combustion of a portion of the fuel fill the fissures, so that the draught is as effectually cut off as in the preceding instance. The portion of coke which is formed, however, is, in consequence of the prolonged heat necessary for effecting the carbonization, so compact that it claims preference in the iron furnaces to all other kinds, provided no deleterious substances be contained in it. Experience has shown that such a coke resists the pressure of the materials in the furnace, and affords a more intense heat when it comes within the region of the blast, than the looser kinds.

Fig. 69.

To insure the production of such a coke, a modification of the oven has been devised to enable the coke manufacturer to char from seven to ten tons at a

time. Fig. 69 represents this form of oven. It is constructed of ordinary refractory materials, and has an area of ten feet square, with a height of about four feet to the springing of the arch or dome of the furnace. To economise the heat, the arch should be so constructed that it will reflect the heat of the fire upon the coal as much as possible, and thereby hasten the carbonization. After the mass of coal has attained a red heat, and the volatile matters are expelled at the chimney, the draught-holes are tightly closed, and the mass is left to itself in this state. Under the action of the confined heat the coke contracts in bulk, and acquires a considerable degree of hardness. When the charge of coke is drawn, the floor of the kiln is cooled down to such a degree as that it will not affect the fresh charge, nor cause a partial distillation of those portions in contact with it, for the coal thus acted upon would yield a lighter and porous coke. This effect is produced by means of a winding or sinuous flue beneath the floor, as seen in *aa*, Fig. 70, which terminates in the chimney, *b*, Fig. 69.

Many other beneficial modifications and improvements are introduced where large quantities of coke

Fig. 70.

are prepared; such as collating several furnaces in a range, by which much loss in the combustion of coal is prevented, owing to the greater amount of heat retained by the materials of the furnace; expedition in charging and discharging the ovens before or after the distillation; and, not the least, the prevention of nuisances by the erection of tall chimneys, which carry the dense volumes of smoke evolved during the action of the fire high into the atmosphere, and, to a great extent, out of the range of vegetal and animal life. Several such improvements may be observed in the coke ovens established at Camden-Town for supplying the railways, especially those of London and Birmingham. Fig. 71 exhibits the disposition of these furnaces, of which there are eighteen or more in a continuous row, and all the volatile products are conducted by a horizontal flue to a tall chimney, which is placed at one end of the line. Like some of those already described, the bed of these furnaces is elliptical in form, the greater diameter being about twelve, and the lesser, eleven feet; the walls are about three feet thick, being

lined with refractory firebrick or clay. The soles of these furnaces are constructed of solid materials, well compacted, the upper layer consisting of firebricks. In

Fig. 71.

the front are the openings, *a*, forming the charging doors, which are three and a half feet wide exteriorly, and about two feet three quarters interiorly; they are closed by cast-iron plates, *k k*, five feet and a quarter in height, by four in breadth, to which counterpoise chains passing over pulleys are appended at the upper extremity, and which facilitate the opening and closing of the door.

The draught of air passing through the furnaces, is regulated by a damper fixed in the horizontal flue; and to prevent smoke from issuing from the mouth of the chimney, a quantity of air adequate to the carbonaceous gases is introduced into the flue, so that the combustion of those products is effected. Each furnace is charged with three and a half to four tons of coal spread over the base. Fire is applied as well at the base as at the front door in the first charge; but after this is charred, and the walls of the furnaces become heated, ignition is produced by lighting some straw or brushwood under the arch of the furnace. Combustion proceeds regularly till the whole contents are at a red heat, and the entire volatile ingredients expelled. This takes place in about forty hours, at which time the dampers are closed, and the mass of coke is left to cool spontaneously, to render it more compact. After cooling, the coked mass is broken, and then drawn out by an iron rake, the handle of which moves on an iron ring suspended before the opening.

Such are the forms of furnaces adopted, and the processes usually followed in the manufacture of coke, but there are many modifications according to the nature of the coal. Some of these are calculated to afford a larger product, whilst others are intended to manufacture a purer coke than can be done by the ordinary method. The principle involved in those improvements which have in view the increase of the product, is such an equalizing of the temperature as to prevent the heat exercising an undue effect on one portion of coals, whilst another may not be fully charred. The advantage gained, however, even by the most careful management, does not, according to the researches of KARSTEN, amount, in the case of the charring of coals, to more than five or six per cent. Generally, the quantity of coke which a coal produces depends more upon its atomic constitution, and the amount of ash which it contains, than upon any other

condition; and without these data, it is nearly impossible to judge what quantity of coke a coal will yield. The analytical tables, given at pages 80, 81, and 82, will throw some light upon the amount of product from many varieties. British coals usually average from fifty-four and a quarter to about seventy-three per cent. American coals examined by JOHNSTON yield about the same quantities. In either case the inorganic constituents, which take from the heating effect of the coke, are included in the calculated amount. By deducting these matters constituting the ash from the coke, and comparing the principal combustible with the content of the original coal, the numbers will stand in nearly the following centesimal proportion for the varieties mentioned:—

	Entire content of carbon in coal.	Pure coke produced therefrom.
Sand coal,	75 to 80	55 to 65
Sinter coal,	80 „ 85	60 „ 70
Caking coal,	85 „ 90	60 „ 80
Anthracite sinter coal, } sand coal,	90 „ 95	85 „ 94

As already intimated, the quantity of carbon in the coal previous to charring is no certain guide to the estimation of the coke which it will produce; for some varieties, very rich in this element, but associated with hydrogen and oxygen to a considerable extent, yield but a low per centage of fixed matter after the fire has exerted its influence upon the mass. To arrive at the knowledge of how much coke any particular kind of coal will afford, recourse must either be had to an accurate analysis of the substance, or a careful observation of the actual mean produce of a number of charges.

The cost of manufacturing coke by the furnace system, averages in England about one shilling and two-pence per ton. In Belgium, the expense amounts to about two shillings and a penny, even when working the large furnaces.

Washing.—Of the improvements for the purpose of producing a better quality of coke, the method of washing lately introduced in France deserves notice. In that country, as well as in Belgium, the veins of coal are intimately blended with shaly matters near the walls, or intersected with such substances, which are in some instances harder, though in others more friable than the coal. In this state, it could not be advantageously employed for coking; and, with a view to economy, it is customary to assort the coal into three classes or qualities. This is done by means of an apparatus called a *gailleterie*, consisting of strong sieves, upon which a stream of water falls. The largest pieces, called *gaillettes*, about two cubic inches in size, are retained in the first sieve; the *gailletins*, or second size, are composed of pieces about one-third of a cubic inch; and the third, or *tails*, consist of fragments smaller than these. From the first, the pieces of schist may be easily removed by picking; but the second, in which considerable quantities of stones and other matters are retained, cannot be so purified; whilst, in the third, or tails, all the earthy, pyritous, and other friable impurities accumulate. M. MARSILLY's experiments showed that the coals from the basins of the Mons and of Valenciennes, when so treated,

and the products converted into coke, gave a result manifesting considerable difference as to quality. The first selection, or *gailletterie*, afforded a good coke, its ashes averaging from six to seven per cent.; the coke from the next selection was not so good, and retained from seven to eleven per cent. of mineral matters. The original coal, when carbonized without any preparation, yielded a product intermediate between these. It was inferred from such results that the substances which affect the purity of the coal are those which are more friable, and that, by a proper course of treatment, they might be concentrated in the *brees* or final refuse of the coal. To effect this, the coals are subjected in some places to a process of washing, similar to that followed in the purification of minerals. In the pyritous coal localities of the Vosges, this process has been practised for a considerable period; but it was not adopted in other collieries till about 1840, when it was introduced into the coal districts of St. Etienne Rive de Gier, and at the Mons

Fig. 72.

Fig. 73.

and Valenciennes. Fig. 72, annexed, shows a side elevation of a simple machine used for this purpose; and Fig. 73 a plan of the same. It is a rectangular wooden trough, divided into two unequal compartments by a partition, A A, which does not extend to the bottom. In the larger compartment, a grate, B B, of osiers, iron wire, or perforated zinc, is fixed, and upon this the coals are cast. The trough is filled with water till it rises to the coals on the perforated shelf, when the washing is proceeded with. This is effected by moving the piston-rod attached to a box, C, filling the smaller compartment, up and down in the water by means of an arrangement of levers, D, as seen in the drawings—a movement which has the effect of forcing the water higher in the larger division of the trough, and of floating the lighter portions of the materials, so as to cause the schistose matter to gravitate to the bottom by the motion produced by the alternate rise and fall of the water. When the action has been continued for a sufficient length of time, the superior layer of purified coal is removed from the under layer of impurities. To render this part of the work less troublesome, another perforated bottom, F F, is fixed over the grate, B B. During the washing, the pyritous and other matters fall through the first, F F, and accumulate upon the second one, whilst the purified coal still rests upon the former. Under favorable circumstances, three men can work off from twenty to twenty-five cubic yards of coal in the space of twelve hours by this machine. The water is drawn off from time to time, and supplied by a proper adjustment of stop-cocks, *et cetera*.

The apparatus employed at Commentry for washing the coal, is, on the whole, simpler than the preceding. Figs. 74 and 75 show a plan and elevated section of the apparatus. The pipe, R S, conducts the water by the connecting pipes, T T T, to the stages where the fuel is washed, and which are represented at A B C D, A' B' C' D', *et cetera*. The coals are deposited in the upper compartment of those beds, as at A B, A' B', and when

Fig. 74.

Fig. 75

the water passes through, the larger pieces are retained by the gratings which divide these from C, C'; while those pieces which pass through the openings of the first grating are retained in the second, and so on, the water finally passing off by the exit pipe, E F. Several other machines have been tried; but the most economical seems to be that of M. BERARD, introduced about six or eight years ago, and another of a later date, invented by M. TROEHLICH.

BERARD'S machine consists of an *elevator*, a *separator*, and what he terms *bancs à lavage*. The elevator is formed of an endless chain of buckets, which lift a certain quantity of the coals from the pit or trough where they are deposited. These buckets empty themselves upon the second part, or the separator. This is a long box divided into compartments by perforated plates, the perforations of which decrease as they extend from the upper to the lower part of the box. By a jiggling or shaking motion given to the whole apparatus, the lumps of coal are divided into four sizes, whilst the shaly and pyritous matters settle to the bottom. While effecting this assortment of the coal and separation of the sulphur compounds, the same movement forces out the several kinds of coal by a side opening into the third part of the machine, or the *bancs à lavage*. There are likewise long rectangular frames, nine feet two inches in length by four wide, provided with perforated bottoms, the holes in which are so small as to retain the pieces of coal thrown upon them. Like the separator, these boxes are divided into compartments, and are kept quite filled with water. In one part works

a piston, by which motion is communicated to the water, so as to cause the material to arrange itself in the order of its density. A current of water made to pass through the box, carries the purified coal beyond the box till it falls into a waggon, in which it is conveyed to its destination; the shaly matter which is left is likewise forced by the current to a trap-door, to which the bottom of the box slightly inclines, and is thus removed. It is said that by one of these machines, the cost of which amounts to about four hundred pounds, and with a daily supply of two thousand gallons of water, not less than one hundred and twenty to one hundred and forty tons are washed per day, at an expense not exceeding one penny per ton.

TROEHLICH's machine consists of a large circular cistern coopered in the ordinary way, and in this a wooden framework, or agitator, is made to revolve by means of an upright shaft driven by suitable gearing and steam-power. The bottom of the cistern is dished, and in the centre is a hole to which a sort of cast-iron conical pocket is fitted; the lower end of the latter is shut by a valve, opening downwards into a canal with a bottom of wire-gauze. Immediately above the bottom three pipes enter at equal distances from one another, for the purpose of supplying water; and, a little above the level of these, at one side, is a rectangular aperture provided with a valve, which opens upon another canal with a wire-gauze bottom. When in operation, the cistern is kept three-quarters full of water, and into this the coals lifted by chain buckets or otherwise fall through a hopper. The motion of the agitator causes the fragments to describe curves of more or less length, and this allows time for them to arrange themselves in the order of their gravity. Owing to the greater density of the schist and pyritic coals, they fall at once on the inclined bottom, and thence through the grating into the pocket above-mentioned, which is emptied from time to time by means of the valve. The fragments of pure coal pass out by the rectangular opening and fall upon the grating, which has an oscillating motion given to it that serves to impel the fuel to a waggon at the end, while the water filters through the grating. The power of this machine is said to be such, that, with a cistern nine feet ten inches in diameter and depth, and a working force of ten horses, two hundred tons of coal could be washed in a day. The cost of such a machine would be about four hundred pounds.

Four to five per cent. of mineral ingredients are thus removed from the coal; but still the latter retains about two per cent. of foreign matters, which, by a more careful mechanical contrivance, may be removed. The coke from this coal, thoroughly purified, commands in France a higher price, of about two shillings per ton. Even for general consumption, the purified coal is eagerly sought, as well for its superior quality as for its cheapness; because, where the coal is at a distance, the transport of six to ten per cent. of its weight of useless material increases its cost price without adding to its value. For many uses in the arts, it is of great importance to have the coal, when much mineral ingredients are contained in it, subjected

to a purifying process. This is the more needed for all such operations as require the use of coke, but in an unequal degree. For railway purposes, the nature of the ash considerably affects the quality of the coke—that is, when it is apt to fuse and run into a slag, as then it impedes the draught, besides injuring the furnace bars. In iron smelting, this property of the ash is not of so much consequence; but the presence of sulphur compounds is deleterious, producing a sulphide of iron which runs into the metal, and impairs its tenacity. Of late years, much pains have been taken with the view of expelling the sulphur from the coke, not by washing, as already pointed out, but by the addition of such ingredients as would, by inducing a double decomposition, liberate this element, or produce compounds with it which are decomposed by the heat. This is the principle upon which the patent of Professor CALVERT of Manchester is founded. He directs to add a quantity of salt to the coal in the coking furnace, proportionate to the quantity of sulphur which the latter contains, so as to expel the injurious element, and thereby obtain a coke of a superior quality. The decompositions which concur to produce this effect are:—the reduction of the iron pyrites—bisulphide of iron—into sulphur and a protosulphide of the metal by the action of the carbonizing temperature; the former of these is expelled, but the latter would remain in the coal were it not that the vapor of the volatilized salt, coming in contact with it, induces a mutual decomposition; the chlorine displaces the sulphur, the former being assimilated by the alkali metal. The chloride of iron formed is further resolved into chlorine and a subsalt, the former of which reacts upon the sulphide of sodium, producing an alkaline chloride, as well as chloride of sulphur, which is volatilized. It is thus that the coal is said to be purified from sulphur, or, at least, the quantity of this element reduced to a very small amount—even the portion which is left, being in the state of sulphide of sodium, a compound which is less liable to decomposition than the sulphide of iron, and which would be found intact in the slag of the smelting furnace, or in the ash from that of the locomotive. The coke manufactured thus, it is said, evolves no sulphurous acid when taken from the oven; neither is sulphide of hydrogen given off when it is extinguished with water in the usual way; nor is sulphurous acid generated by its combustion in the cupola or furnace. Even ordinary coke may be improved for the wants of the smelter, by adding a certain quantity of chloride of sodium in the cupola. The reaction which takes place in this case is the same as that previously explained.

As already stated, it is evident that coke, like the coal itself, will exhibit considerable difference, both in the nature and per centage of its constituents. A glance at the analytical tables, submitted at page 80, will show the causes of this difference. It will, therefore, be unnecessary to transcribe here analytical results of the composition of coke, further than may be sufficient to indicate the usual qualities supplied to the manufacturer. Of these, nineteen analyses are subjoined:—

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.

The heating qualities of coke, although easily inferred from the per centage of carbon, will be further considered when the relative value of different kinds of fuel comes to be examined.

PATENT FUEL.—In most of the operations of coal-mining, as also in coking establishments, much refuse accumulates which is frequently very rich in combustible matter; but owing to its being in small dust or powder, it cannot be used in the furnace by itself. A similar waste attends the manufacture of wood and peat charcoal, and without the aid of some cohesive matter, this considerable portion of the original fuel becomes useless.

Attention has for a long time been directed to the means of economizing such products in countries where fossil fuel is scarce, and this has not been confined to the *brees* or small refuse matter of the charcoal manufactory, but has been extended to such bodies as sawdust, wood shavings, and other combustibles. In the district adjoining the Caspian Sea, where petroleum springs are abundant, the inhabitants manufacture a fuel, by impregnating clay with the combustible fluid; the clods are afterwards burned in an ordinary hearth. By the gradual evaporation and combustion of the carbides of hydrogen, a fire of considerable intensity results. Indeed, the various contrivances which now come under the notice of the chemist, with a view to the production of artificial fuel, are little more than a copy or counterpart of the method adopted by the Orientals for solidifying the naphtha. The Norwegians have long economized the large quantities of sawdust which they produce, and convert it into a household fuel, by incorporating it with ordinary clay and a little tar, and moulding the whole into bricks. Of late years attempts have been made in this country to introduce a similar practice, by parties who proposed to employ sawdust, brushwood, shavings, spent tanner's bark, and the like substances, in the manufacture of fuel and combustible gases; but hitherto the speculation has not succeeded. The principal ingredients which are taken for the production of artificial fuel are small coal or slack, friable anthracite, the refuse or *brees* from charcoal and coke ovens, and peat—all of which are mixed with more or less pitch tar, or refuse fatty bodies. The product of some of these ingredients is found in many respects superior to natural fossil fuel, and may be used where the highest temperatures are required. For generating steam, a fuel carefully manufactured with small or refuse coal and pitch, or sub-

stances of a similar nature, is often preferred to ordinary steam coal, as it offers conveniences for stowage which coal does not, whilst its heating power is equal to, if not greater than, that of the mineral fossil.

In France, a very fair quality of charcoal is prepared with the refuse from the charcoal furnaces, by mixing it with other substances, such as charred peat, spent tan, and the like, adding tar or pitch. The course of procedure is to grind the solid with the fluid ingredients into a homogeneous pasty mass, which, after being moulded and dried in the air, is subjected to heat in close vessels, and all volatile gases

expelled. Fig. 76 represents the mill employed for mixing the charcoal, after being reduced to coarse powder by a preliminary grinding, with the tar or other liquid. It consists of two fluted cast-iron rollers, A A', connected with an upright central shaft, B, bearing a mitre-wheel, c, which is turned by a pinion, D, gearing into it. The rollers move upon the bed-plate, H H, on which the materials are laid and submitted to the action of the revolving masses till thoroughly mixed. A scraper, O, follows the rollers in the usual way, in order to bring the substances within their range, and by means of another, M, the material is discharged at the slide, F, into the box, E. About six or seven thousand gallons of the mixture are prepared by this machine in twenty-four hours, and the force required to work it is calculated as one horse. From seven to nine gallons of the tar is doled to about two hundred-weight of charcoal powder.

After the mixture is prepared, the pasty mass is moulded into appropriate forms by a machine such as that sketched in the annexed Fig. 77. By this machine the fuel is formed into quadrangular or circular masses by moulds into which it is introduced, and

therein submitted to pressure by means of a heavy log or beam of wood, which carries pistons that work

Fig. 77.

into those frames. In the above figure, the beam is represented by *AB* moving on the uprights, *GH*, *GH*, which keep it in its place by the eccentric motion communicated to the rods, *IJ*, *IJ*; *a*, *b*, *c*, *d*, *e*, indicate the pistons which press the material in, and discharge it from the moulds, *f*, *f*, *f*, *f*, *f*. Two women are constantly employed in filling the moulds; and whilst the one set are being pressed and discharged by the pistons, *a*, *c*, *e*, the others are replenished. When the beam, *AB*, is raised, the filled moulds are brought under the pistons by a horizontal motion communicated to the casting, *EE*, by the pinion and wheel, *L*, *K*; on the descent of the beam, these are in turn discharged, the others being filled in the meantime, and the motion of *EE* reversed. In this way the operation of moulding goes on without interruption. An equivalent of six horse-power is required to work this machine, but with it one man and four women can produce about four hundred and fifty bushels of the fuel in a day.

After the moulding, the next operation to which the material is subjected is the drying, which is merely an exposure of from two to three days to a current of air.

The carbonization of the bricks is effected in a kind of muffle furnace, shown partly in section, and partly

Fig. 78.

in elevation, in Fig. 78. The muffle in this furnace is about four and a half inches thick of refractory material. It is heated by a fire at *B*, the flame from

which circumscribes the whole of the muffle. The products of combustion pass behind the muffles by the channel, *CD*, but return to the front by the flue, *E*, and ultimately depart by the openings, *f*, *f*, into the subterranean channels, *g*, *g*, leading to the chimney at the back. The bricks or moulds, which are generally four and a half inches in length, by one and a half in diameter, are packed in the carbonizers, which may be sheet-iron boxes, *HHH*, or cast-iron cylinders, *III*; these are fixed on trucks, to facilitate their introduction and withdrawal from the muffle by a door in front of the case, lined with firebrick and refractory clay, which may be opened and shut at will. This door is shown at *K*, and when the carbonization is proceeding, all crevices in it are carefully stopped by clay luting.

The first effect of the heat is to eliminate moisture from the charring mass; this is followed by some carbides of hydrogen, all of which escape from the cylinders or boxes by small apertures, about the time that the cylinders are beginning to become red-hot. Air is then admitted cautiously at *M*, *M*, whereby the evolved gases are burned, giving out as much heat as is sufficient to complete the operation. By having a series of eight muffles and cylinders, two may be charged every six hours, the material being charred in a day. When no more flame is observed in the space, *C*, examined through *M*, the workman knows that the charring is completed, and the cylinders are then withdrawn.

Waste cuttings, brushwood, and such materials as could not be employed in the manufacture of ordinary charcoal, may be carbonized, and then turned to profitable account in the manner just described.

The same principle is developed in the manufacture of patent fuel from refuse coal or slack, and also from the waste matter of the coke ovens. In either case, it is necessary to mix them with substances which will give a sufficient consistency to the mass, to cause the particles to adhere whilst coking or burning in the open or furnace grate. In selecting the cementing material, there are some who do not confine themselves to oleaginous, fatty, or tarry matters, but employ also loam, hydrate and sulphate of lime, and various other mineral substances, whilst others—and doubtless this is the best course to adopt—discard the use of all such bodies; and, by a judicious admixture of two varieties of coal, or by operating upon the coal in a particular way, cause it to adhere, and so bring it into such a form as will admit of its being burned as ordinary fuel, or coke. The most important of the patent fuels will here be alluded to.

WYLAM directs, in his patent for the manufacture of artificial fuel, that small coal be mixed with pitch, and the compound afterwards moulded.

The proportions in which these ingredients are taken, are four parts of slack to one of pitch. By means of edge stones, or other machinery, the pitch and coal are ground together, or otherwise mixed, and the mass is put into a large hopper, from which it passes into a retort. This arrangement is seen in Fig. 79, where *MM*

are the receivers or hoppers, from which the mixture is carried into the retort by the plain rollers, R R R, moved by the shaft, N. By the same agency, motion

Fig. 79.

is communicated to an Archimedean screw, Q, which works within the retort, and the matter is discharged at each revolution of the screw as fast as it enters the retort from the hopper. As the retort is maintained at a red heat by the hot air in the flue, T, the material becomes more or less liquefied during the passage from one end to the other.

This pasty mass having fallen into the receiver, S, is agitated by the arms, r r—Fig. 80—to prevent it

Fig. 80.

hardening into lumps before it is moulded. The moulds, B B, are ranged upon a movable oval table, A, to receive the pasty mass. Into these moulds, rams, connected by pistons, v y, are forced, by means of the pressure exerted upon them in the cylinders, u x, and which are worked by water. The table is made

to revolve by means of a lever, z, by the motion which the piston, y, communicates to it; and while in its revolution the filled boxes are conducted under the rams of the piston, v, those of y discharge the formed masses into a receiver, where they are further impressed with the maker's name.

If the pitch be not well distilled, and a portion of the oleaginous constituents are retained, the fuel, when stowed where the temperature is somewhat elevated, is apt to ignite spontaneously, in consequence of the evolution and oxidation of those matters. The tendency to this is always greater when fatty matters or oils have been used with the small coal. Numerous instances of the spontaneous combustion of artificial fuels, and even of coals, have been traced to this cause. Such a disaster occurring in the hold of a vessel at sea, is almost certain destruction to the ship.

the ignition in the grate. A longitudinal section of the furnace and retort for heating and exhausting the fuel of its more inflammable constituents, is shown in Fig. 81, where A represents the retort, or the chamber wherein the fuel is heated, furnished with sliding-doors and rails, upon which the carriages loaded with the fuel run. Caloric is communicated to the matter in this chamber by means of superheated air forced in by the openings, P P, from the furnace beneath. The gaseous products are conveyed by a pipe, B, and dip-pipe, D, into a main, E,

Fig. 81.

arranged nearly in the same manner as in the manufacture of coal gas. By means of the exhausting apparatus—Fig. 82—the volatile products are drawn off. This consists of two cylinders, H H, open at the bottom, and working in vessels, I I, containing water. The cylinders are connected by a chain with the beam, J, and this again with the connecting-rod, K, by the motion of which the ends of the former are alternately raised and lowered, and consequently the cylinders, H H, also. At each elevation, the gases disengaged flow from the main, E, by the branch pipes, L L, into one or other of these cylinders; and as this cylinder is made to descend, the gases are forced out by the pipes, N N, which dip into the tank, O; they are secured from being driven back into the main by a valve, M M, in connection with the pipes, L L, which opens into the cylinders when the pressure is removed, and shuts when this is exerted.

Fig. 82.

At the expiration of six to eight hours the operation is finished, and a fresh charge is introduced.

At Blanz, the waste coal is worked into a patent fuel in the following manner:—The coal is screened or purified from fragments of pyritous and shaly substances, by placing the matter upon a metal sieve, fixed in a large vat, communicating with a pump by means of a large pipe. When the pump is worked, the water is agitated in the vat, and this agitation causes the matter on the sieve to arrange itself in the order of its density, the heavier particles falling through to the bottom of the vat. The principle of this washing process is precisely the same as that represented in Figs. 72 and 73. After the matter remaining on the sieve is drained, it is removed and crushed between rollers, so as to render it more homogeneous. The coal thus crushed is mixed with seven or eight per cent. of tar, and moulded into bricks. The apparatus by which this is performed is shown in Fig. 83, where B represents the furnace by which the materials are heated, and A the ashpit. D is an arch which serves to depress the flame, so that it shall pass the bridge, E,

and spread itself over an extended surface at *f f*, for the purpose of heating a metal cistern, *m m*, which turns on a pivot, *i*, and is moved by a pinion, *r*, working into the toothed edges, *h h*, of the cistern. A flue carries off the smoke to the chimney. The coal, when thrown into the furnace, is spread evenly by a rake,

Fig. 83.

k k, attached to rods, *l l*, that pass through the masonry of the furnace, and are secured exteriorly by nuts. A boiler, *v*, placed over the arch of the furnace holds the tar or pitch in a fluid state, and the necessary proportion may be let into the charge of coal in the furnace by a valve, *w*, at the bottom, which may be closed at pleasure by means of the rod, *u*. From this valve it flows along the pipe, *y y*, which runs the whole length of the rakes, *k k*. In this way, a comminution of the tar and coal is effected; and when the operation is judged to be complete, two scrapers are lowered, which collect the material, and as soon as the cistern has made about two-thirds of its revolution, two trap-doors are opened, and it falls into a receptacle, *p p*, below, whence it is afterwards removed while plastic by the door, *q*, and pressed into bricks by the hydraulic machine.

Several other patent processes for solidifying small coal and tar into a substance fit to be used as fuel, differ but slightly from the foregoing. The process of Mr. BESSEMER is considerably superior to any of these, as it enables proprietors to convert *the whole of the combustible material* into first-class coal, without suffering the loss which is invariably attendant upon colliery operations. It consists in heating small bituminous coal to a temperature at which it fuses, and while in this state moulding it into convenient shapes. By this means the use of mineral, tarry, or oleaginous contents are dispensed with, and a fuel is produced nearly equal in heating qualities to the round coal of the working, and much more convenient for stowage, from its being in regular shapes. In this operation, a series of very ingenious contrivances are brought into requisition, and made to perform the work with admirable regularity. The apparatus by which these improvements are effected is shown in the annexed engravings—Figs. 84, 85, and 86. Fig. 84 is a longitudinal section of the furnace and retort; Fig. 85 a longitudinal elevation of the pressing machinery,

showing also the end of the furnace; and Fig. 86 a plan of the pressing machinery, with part of the furnace and retort.

In Fig. 84, the furnace, *a a*, contains a retort, *b b*, which is represented broken, to indicate that it may be of larger dimensions than here shown. For convenience of erection, it should be made of three lengths united by flanges, and the joints made tight by iron cement. One end of this retort projects from the furnace, and overhangs a part of the pressing apparatus, as shown in Fig. 85. It has a shelf or partition, *c c*, extending nearly to its whole length, and in a tangent line with the upper surface of the polygonal drums, *e* and *d*. Over the latter, two chains are made to pass, which are connected by broad plates of iron, *g*, with flanged ends, which are riveted to the single links of the chain; the edges of the plates, *g*, which project, are beveled so as to form a scraper. Motion is given to this chain by the drums, *e d*, which have projections,

z, that fall into the spaces between the binding plates, and thus carry them round the drums. On the upper side of the retort there is fixed a hopper, *j*, in the lower part of which, where the slack or coal-dust is placed, is fixed a feeding drum, *k*, with ribs or leaves

Fig. 84.

closely fitting the tube of the hopper. Appended to the side of the hopper are bosses, in which the shaft, *n*, of the feeding drum revolves. The action of this part of the apparatus is as follows:—A fire having been lighted in the fireplace, *s*, the products of combustion pass under the retort, and escape at the open end of the flue, *s'*, whence they may be conducted spirally about a boiler, for the purpose of generating the steam required to work the apparatus. When the economy of the waste heat comes to be considered, it will be preferable to set the retort so that the heat may ascend a narrow space between its sides and the walls of the furnace. An enlargement of the fire-chamber is shown at *s'*, for the purpose of transmitting radiant heat to the under side of the projecting part of the retort. The temperature of the furnace having brought the retort up to a heat approaching redness, the feeding drum is put in motion, when the small coal or coal-dust will be deposited upon the shelf, *c c*; but the motion of the chains and scrapers will move it along the shelf; and, as each scraper comes in turn under the feeding drum, the coal which has fallen between each of them will be carried forward to the right end of the shelf, off which it falls on to the lower and hotter part of the retort, occupying here

as before the space between the scrapers. It will be observed that the entire weight of the chains and scrapers rests on the bottom of the retort, and hence, by the constant passage of the former, the coal is prevented from sticking to it, and rendering its interior surface uneven. This movement not only prevents the caking of the coal to the wall of the retort, but it turns it over repeatedly, thus presenting to the heated surface fresh portions; the effect of the heat is thus equalized, and the fuel is conducted in a softened state over the opening, *f*, in the lower side of the retort, and falls into the receptacle, *t*, where it is submitted, in regular course, to compression in the apparatus, represented in plan in Fig. 86, and in elevation in Fig. 85. In these figures, *A* is the

Fig. 85.

there supported by trunnions, working as usual in plummer-blocks bolted to the two frames, *v v*. In order to regulate the motion of the apparatus, fly-wheels, *F*, are keyed on to each end of the crank. A stout connecting-rod, *K*, is made with a double gib-head, *h h*, to receive motion from the same crank-throw. The other end of the connecting-rod, *K*, is jointed by a gib-head and pin to two lugs, which project from the stout cross-head, *I*; the ends of the cross-head slide in guides, *T T*, which are secured by bolts to the flange of the bed-plate. There are three plungers, *L L L*, keyed into the cross-head, and working in cylinder holes bored truly through the massive block of iron,

N, which is secured by bolts to the bed-plate by a flange, and keyed up between steps cast on the same. The upper part of the cylindrical block, *N*, has a large opening made in it, through the bottom of which the plungers, *M*, move. Immediately over this opening is the receptacle, into which the softened coal falls from the retort. Another set of plungers, *R R R*, work in the cylindrical holes of the block, *N*, at the opposite end to that occupied by *MMM*. Two guide-bars are bolted to the flange of the bed-plate, and have holes bored in them of sufficient size for the plungers, *R R R*, to work in. The latter are made large enough to work through both these guides, so that when they

Fig. 86.

are entirely withdrawn from their respective cylinders in the block, *N*, they will be so guided as to re-enter them without difficulty. The plungers, *R R R*, are keyed to a cross-head, *U U*, on the ends of which are fitted, with gib-heads, two long connecting-rods, *s s*, seen in Fig. 86, the opposite ends of which are likewise

furnished with gib-heads, and work on crank-pins, which project from one of the arms of each fly-wheel. These crank-pins are so placed with reference to the central crank-throw, that the latter forms an angle of 45° with them; that is, the one is the one-eighth part of a circle in advance of the other, and thus the action of

their respective plungers will be such, that they will alternately approach and recede from one another at the end of their respective strokes.

The motion of the chain and feeding drum is regulated by passing a strap over one of the fly-wheels; this strap works on the drum, *F*, on a shaft, *m*, which carries a worm that works upon the upper side of a wheel, keyed on to the shaft of the polygonal drum, *d*, Fig. 84; another worm works into the lower side of a wheel, keyed on to the axis of the feeding drum. From this description, the reader will understand how the steam piston, acting upon its crank, will put in motion the whole apparatus, and that this motion will be regulated by the fly-wheels; also the manner in which the cross-heads will be acted upon by their respective connecting rods, and likewise how the sets of plungers, *L L L* and *R R R*, are made to reciprocate in their respective ends of the block, *N*. Supposing the operation commences when the crank, *D*, and its connecting-rod are in a horizontal position, and the plungers, *L L L*, withdrawn as far as possible from the block, *N*; if one-eighth of the revolution be now made, the plungers, *L*, will be moved forward a little, and the crank-pins will have risen to the horizontal level, and brought the plungers, *R*, nearer towards the centre of the block, *N*. Upon turning the crank an eighth further, *L* will advance a considerable distance, being at half stroke, and at the same time the plungers, *R*, will have receded to their starting position. Here it must be observed, that the soft coal which was carried forward by the plungers, *L*, is compressed between the opposing ends of the two sets of plungers. In this position of *L* and *R*, there is a small space between them where any surplus quantity of coal may squeeze out, before it is made to enter the close part of the cylinder; after which they will approach a very little nearer to each other, and thus give the final pressure. If another eighth of a revolution is now made, the relative position of the crank and crank-pins will give a quicker motion to the plungers, *R*, which will commence receding from the plungers, *L*, and thus leave no pressure on the solidified lump of coal. If the pressure were not thus relieved, the lump of coal, as it merges from its cylindrical hole in the block, *N*, would be broken, there being no longer any circumferential support for it. Another eighth of a turn will complete a single stroke of the plungers, *L*, and have entirely expelled the block of coal, which then falls down into the receptacle, *t*, the plungers, *R*, having receded still further, and allowed ample space for the block of fuel to fall.

Another eighth of a revolution will commence the return stroke of the plungers, and by following on in the same way until one complete revolution is performed, the respective plungers will again have resumed their original position, and be ready to renew the operation.

If three plungers are made use of, as here represented, three blocks or cylinders of fuel, of equal length and diameter, will be formed at each complete stroke of the engine. As there is a tendency in the block of fuel to stick to the plungers, *L*, a detaching frame is placed at the end of the machine where the blocks are expelled.

This consists of thin bars of iron, fixed on an axis, the ends of which work in lugs on the guide bar, *U U*; the other ends of the bars are connected by a rod, and upon the cross-head there are bolted two small frames, which carry rollers, upon which the bars rest. When the cross-head, *s*, moves backward, and allows the blocks of coal to be projected outwards by the plungers, *L*, then the rollers will pass under the inclined part of the bars, and descend by their own weight, and the rod will come in contact with the blocks of coal, and detach them from the end of the plungers; if they should adhere, the reverse motion of the cross-head will again raise up the bars in readiness for a repetition of the process.

From what has been before stated in reference to the softening process by heat, it will have been understood that the coal-dust may be made to traverse the shelf, *cc*, where it will receive a preparatory heating, and afterwards traverse the bottom of the retort so quickly, as to produce such a slight effect upon the bituminous portion of the coal, as only to soften it a little, and render it fit for the operation of compressing into solid lumps possessing the general properties of the coal from which it is produced. One of the objects for which these operations are performed, is to alter and modify the composition of the resulting fuel, by driving off certain of the volatile constituents of the coal, and thereby rendering such fuel more fitted for certain processes in the arts than ordinary coal. To effect this object, the speed of the feeding and polygonal drums may be adapted so as to subject the coal to any assigned period of operation, and the intensity of the fire being also regulated, the extent to which the distillatory process is carried will be under perfect control. The gaseous matter eliminated from the coal, as it traverses the hottest part of the retort, over the fire-plate, *s*, will have to pass over the surface of the coal which is advancing in that direction, and help to heat it, while it also assists in transmitting caloric to the under side of the shelf, *cc*. Having contributed in this way to heat the materials, it ascends through an opening at the end of the furnace, and passes along over the coal-dust spread upon the shelf, and farther assists in heating it, and finally makes its escape through the pipe, *x*.

This pipe should have an elbow descending in the manner usually adopted in gas-works, and known as the hydraulic main. In this vessel the liquefiable portion of the volatile matters will be condensed, and the gas may be passed to a gasometer, where it may be stored for use. The fuel resulting from this partial distillatory process will be found to be less fusible in the furnace than ordinary raw coal, and consequently the caking in the furnace will be prevented. To divest the coal of as much of the volatile gases at as low a temperature as possible, an air-pump, constructed in the manner generally employed for exhausting sugar vacuum pans, is used. The pump is connected with the pipe, *x*, and by the application of steam or other motive power, the retort is kept in a state of exhaustion, which should, if possible, be equal to twenty-four or twenty-five inches of mercury in the barometer.

By this exhaustion, the liberation of the volatile gases from the cells and interstices of the fuel is facilitated.

and the residuary matter is rendered much more dense and compact when subsequently pressed. When the air-pump is used, the eduction valve must be made to communicate with the hydraulic main, so that the gaseous matters pumped out may pass off into the gasometer. Instead of applying fire directly to the under side of the retort, as shown in Fig. 84, superheated steam may be used for softening the fuel. When this plan is adopted, a set of cast-iron pipes are arranged in a furnace in the same way as is now commonly used for heating air and steam for blast and other purposes. Into one end of this series of heating pipes, the waste steam of the engine is allowed to pass, and the pipes being kept at a red heat, the steam will acquire a very high temperature, and in this state is to be supplied to the interior of the retort, to soften the coal. The retort, which may be constructed as already described, will not, in the event of steam being used, require any flue beneath it or fireplace, but it ought to be enveloped in brickwork, or some other non-conducting material, in order to retain the heat as much as possible. The steam-pipe should open into the retort at the hopper, *t*, the outlet for the waste vapor and gases being the pipe, *x*, leading to the hydraulic main and gasometer.

Besides these, several other patents have been obtained for the manufacture of patent fuel from waste combustible materials, many of which are but of little interest.

ANALYSIS OF FUELS.—Having explained, in the preceding pages, the nature of the more commonly occurring fuels, as well as the processes by which certain varieties of them are prepared, to render them better suited for particular uses, it remains only to describe briefly the methods of analysis which are usually followed when determining their constituents, and indicate the way by which their value, in point of heating effect and practical working in the furnace, may be arrived at.

There are various processes whereby the composition of wood, charcoal, *et cetera*, may be found. Many of these are so simple, that any person having only a partial knowledge of chemical manipulation, can conduct them with sufficient accuracy; several, on the contrary, require the experience of the advanced analyst to insure success. The examination, with reference to the quantities of carbonaceous and mineral matters, may be made by simply burning a weighed portion of the fuel in a tared crucible of platinum or porcelain till all blackness disappears, and only the white or brownish ash remains. The difference between the weight of the latter and that of the original substance, will give the proportion of combustible ingredients. But before an estimate of the value of a fuel can be formed, something more than the preceding is necessary; and this will be evident from the consideration of its different applications in the arts and manufactures. For instance, the charcoal or coke manufacturer is chiefly interested in the quantity of carbon which he can retain after modifying the wood, peat, or coal, by the action of heat; he has little regard to the quantity of volatile or liquid products which can be generated from them. The gas-maker, on the contrary, is mainly desirous to secure such materials as

will yield the largest volume of gas, whereas the liquid products of the distillation, and the coke, engage only a secondary part of his attention.

To find in the simplest and readiest way whether a fuel, such as coal, is best adapted for one or other of these applications, it is necessary, in the first place, to dry the weighed sample thoroughly, and to find, by again weighing it after desiccation, how much moisture it contained. The heat of a water-bath will serve for this purpose, but an air or oil-bath kept at a temperature of about 300° will answer better. Having determined the quantity of water, the weighed sample must next be subjected to a full red heat in a crucible carefully covered to exclude the air; and, for greater security, the latter is placed in a Hessian crucible, also covered, and containing calcined magnesia. The whole is then introduced into the furnace. The magnesia serves as a support for the crucible containing the substance to be examined, as well as to prevent contact with the outer vessel. The fire is raised to bright redness, and after being maintained at this temperature for an hour, the vessels are withdrawn from the fire, and the enclosed crucible taken out, wiped clean, and weighed. The loss which appears on weighing will represent the liquid and gaseous matters present, and the residue the coke or charcoal which the sample yields. If the per centage of mineral matters be already found, the quantity of carbon in the coke is estimated by deducting this per centage from that of the total amount of coke; but if the proportion of ash has not been ascertained, the crucible containing the coke is heated over a gas-lamp or in the muffle of a furnace, so arranged that a current of air shall circulate through it, till all the charcoal is consumed.

In this way, the quantity of moisture, of volatile matter—consisting of permanent gases and liquids—of coke, and of ash, which a fuel yields, is ascertained; and from them an average inference as to the value of the substance for the production of coke may be deduced, though not for gas-making, because it leaves doubtful how much of the volatile matter consists of inflammable gases, and how much of fluid products. When a very exact knowledge of a fuel is required, nothing short of an elementary analysis can be satisfactory; and this must be coupled with another, showing the quantities of the different products derived from the fuel, when acted upon by heat, out of contact with air. Even both these fail in some cases to give the information required in relation to many applications of the combustible.

By an elementary analysis, is understood the determination of the simple elements of matter entering into the composition of a substance. To enter fully into the particulars of such an analysis would rather confuse than enlighten the reader who may not be conversant with analytical chemistry, and those who are practised in organic analysis do not require a detailed description. A mere outline of the process will, therefore, be given. The first thing to be done is to rasp or abrade a portion of the substance into as fine a powder as possible. A certain weight of this powder is then to be desiccated either in the water-bath or over sulphuric acid in an exhausted receiver, or by

passing over it dry air partially heated. The loss in either case will indicate the moisture it had contained. About ten grains of the dried matter are then taken, and intimately mixed with eight or ten times the quantity of chromate of lead or oxide of copper in a heated mortar, and immediately introduced into a dry combustion tube of hard German glass. Care must be taken that the oxidizing agent, whether it be chromate of lead or oxide of copper, be subjected to a red heat immediately before its admixture with the combustible, to insure the absence of water; also, that twenty or thirty grains of dry chlorate of potassa are put into the inner part of the combustion tube, and an inch or two of the oxidizing agent, before the substance to be examined. Having rinsed the mortar with a fresh portion of the chromate or oxide, and added this to that in the tube, the latter is tapped in a horizontal position on the table, in order to form a channel in the upper part for the gases and vapors to flow over. A few fragments of copper turnings are placed in the front part of the tube, and then a little asbestos. Having introduced these, the mouth of the tube is secured by a cork fitted with a small piece of tubing for connecting it with a poised chloride of calcium tube, in which to intercept the water generated during the combustion. To the latter, another tube filled with a solution of caustic potassa, specific gravity 1.26, and commonly known as a LIEBIG'S apparatus, also previously balanced, is joined by means of a caoutchouc connector. The success of the experiment will very much depend on the connections of the various parts being quite secure. During the fitting of these parts, the tube may be placed in the combustion furnace. As soon as the several parts are carefully adjusted, a few fragments of ignited charcoal may be laid on the sealed end of the tube containing the chlorate of potassa, and after the air of the apparatus is replaced by oxygen, the combustion is commenced by applying red-hot charcoal to the front of the tube. Care must be taken that the development of gas be not too rapid, as in this case portions may escape absorption; neither, on the other hand, must it be too slow, lest a vacuum be formed in the combustion tube, causing a reflux of the solution of potassa, which would be fatal to the experiment. A steady even stream is kept up by extending the ignited charcoal to fresh parts of the tube as the evolution begins to slacken. After that part of it containing the combustible has been brought to a red heat, and no more gas is evolved, the fire is applied gently to the part containing the chlorate of potassa, so as to produce a gradual stream of oxygen gas, the combustion tube being still kept at a red heat. This has the effect of forcing over into the absorbing apparatus any carbonic acid and aqueous vapor which may remain, and at the same time insure the entire combustion of any particles of charcoal that may not have been exposed to the full heat. Finally, the closed point of the tube is broken, and a U-shaped tube containing fragments of pumice-stone, saturated with sulphuric acid in one limb, and pieces of hydrate of potassa in the other, is connected with it; suction is then applied at the open limb of the potassa apparatus, to draw over all carbonic acid and moisture; after which the chloride of calcium tube and bulbs are

detached and reweighed, and the increase in each case noted carefully, as from this the carbon and hydrogen of the substance is calculated.

The calculation is founded upon the data afforded by the composition of water and carbonic acid—namely, that nine parts of the former contain exactly one of hydrogen, and twenty-two parts of the latter six parts of carbon. All the water resulting from the combustion of the hydrogen with the chromate of lead, *et cetera*, is retained in the chloride of calcium tube, and the whole of the carbonic acid, generated under similar circumstances, is absorbed in the bulbs; hence, when due care has been exercised, the results are very accurate. Sometimes a second chloride of calcium tube is attached to the apparatus for absorbing the carbonic acid, when the amount of nitrogen in the sample is appreciable, with the view of arresting the aqueous vapor which this non-condensable gas carries with it from the potassa liquor. It will be evident, indeed, that, in almost all cases, this precaution ought to be adopted; for even when no nitrogen is contained in a substance submitted to organic analysis, the air drawn over at the termination of the combustion becomes loaded with moisture in passing through the bulbs, and so far the weight of the latter is reduced, on which account the amount of carbon found is less than the true quantity; but by attaching a second chloride of calcium tube, filled with fragments of this salt after being fused, and which should be weighed before and after the operation, and adding the gain to that of the bulbs, this error may be prevented.

Instead of compounding the substance with a solid oxidizing agent as in the manner described, it may be introduced at once, provided it has been previously dried, into the combustion tube in a tolerably coarse state, and a stream of pure dry oxygen gas passed over it. The tube should be open at both ends, one of which is to be put in connection with the reservoir of oxygen, and the other attached to the usual absorbing media. It is necessary that the oxygen be entirely free from carbonic acid and moisture, and for the greater safety it should be transmitted through a U-tube, holding in one limb fragments of fused chloride of calcium, and in the other pieces of solid potassa, before entering the combustion tube. In this process it is absolutely essential that the potassa apparatus should have a chloride of calcium tube connected with its escaping limb, otherwise the excess of oxygen would carry with it considerable quantities of aqueous vapor, and so reduce the indication from which the carbon is to be calculated. Connection of the several parts being made, a gentle stream from the reservoir is allowed to flow through till all the air is displaced. As soon as this happens, heat is applied to the tube by placing incandescent charcoal around it in the usual progressive way, the current of oxygen being still maintained, till it assumes a red heat, or nearly so, and it is kept in this state till all the carbonaceous matter of the substance operated upon is consumed. Gas may be very advantageously substituted for charcoal in conducting an operation of this kind. When all combustible matter is eradicated from the tube, the fire is slackened, and the current of oxygen maintained for a short time. The parts for

absorbing the water and carbonic acid eliminated during the foregoing process are detached, wiped, and balanced, as already detailed, and the hydrogen and oxygen are calculated from their augmentation in weight.

To estimate the nitrogen, a second combustion is in some cases requisite. When the quantity is ascertained volumetrically, the work may be accomplished at one combustion, by establishing a connection between those parts in which the hydrogen and carbon are retained as water and carbonic acid, and an apparatus for measuring the gas. A long combustion tube is required in this instance, so as to admit of a few inches of it being filled with copper turnings, to decompose any bin oxide of nitrogen which may be produced during the action of the heat. The nitrogen traverses the chloride of calcium tubes as well as the potassa bulbs, and finally enters the graduated tube, and displaces the mercury with which it is filled. When the operation is finished, some oxygen is generated from the chromate of potassa, in order to force over all the nitrogen and other gases remaining in the apparatus. A portion of this oxygen enters the graduated jar or tube, and must be removed before reading off the volume of nitrogen. For this purpose, after reading off the volume of mixed gases, a quantity of hydrogen equal in bulk to this mixture should be added, and as soon as diffused a measured portion should be transferred into an eudiometer, and exploded by the electric spark. By noting the reduction in the portion taken, the quantity or volume of oxygen in the whole may be ascertained, from the knowledge that one-third of the decrease is oxygen. Deducting the volume of oxygen thus found from that of the mixed bulk of oxygen and nitrogen, the remainder will be the volume of the latter in the portion of the substance submitted to combustion, and from which the weight is deduced, since, at a barometric pressure of thirty inches and a temperature of 60°, the weight of one hundred cubic inches of nitrogen is 29.2914 grains.

WILL and VARRENTRAP's method is a considerable improvement upon the system of analysis pursued in the determination of nitrogen, inasmuch as it dispenses with the use of mercurial troughs, graduated measures, barometers, thermometers, *et cetera*; it is besides much simpler and less laborious, for whilst numerous corrections have to be made for temperature, pressure, and the like in the old process, by this the work is most accurately performed by simply weighing. It is based upon the property which the fixed alkalies have, of converting nitrogen, in whatever state it is contained in a substance, into ammonia, when aided by heat. The ammonia is fixed by an acid—generally hydrochloric—and subsequently in the form of ammoniochloride of platinum, which is collected, dried, and weighed, and the nitrogen calculated therefrom; 222.5 parts of the salt representing fourteen parts of the gas.

The agent used for the conversion of the nitrogen into ammonia is soda-lime, which is prepared by slaking caustic lime with a concentrated solution of hydrate of soda. The compound should be thoroughly dried, and kept in well-stoppered bottles. In the cold it does not

act upon the nitrogenous element of the substance to be analysed, and, therefore, both bodies may be mixed in a mortar, provided they are thoroughly dry, without any fear of ammonia being disengaged or loss occasioned. The ordinary combustion tube answers the purpose, and the course to be pursued is the same as that already mentioned for mixing the ingredients and heating, *et cetera*. The details of the estimation of the ammonia, quantitatively, have been already stated at page 198, Vol. I., to which the reader is referred.

The modification of this process, introduced by ULLGREN, may be advantageously noticed here. The combustion with the soda-lime is essentially the same in this as in the preceding operation; the only difference lies in the manner of condensing the ammonia adopted by this chemist. Fig. 87 represents the form of apparatus employed. In this cut, A and B are two U-shaped tubes, in the first of which the connector from the combustion tube opens; the upper portion of the first limb of the part A is charged with a plug of asbestos, *a*, and in the remainder, *b*, small pieces of hydrate of potassa are placed; fragments of glass occupy the bend, *c*, and the second limb, *d*, is filled with little lumps of caoutchouc. A tube, *e*, bent at right angles, and passing through perforated airtight corks, connects A

Fig. 87.

with B, which is filled with dry sulphate of zinc, and which should be accurately weighed before the experiment. The asbestos in the portion *a* prevents solid particles from passing by the force of the vapor upon the potassa; the latter absorbs the carbonic acid and water, leaving the ammoniacal vapor and hydrocarbon gases to traverse further; the pieces of caoutchouc take up the combustible products, so that only the ammonia enters the tube B, where it is completely absorbed by the zinc salt. To insure accuracy in this operation, it is directed that the part A be immersed in water marking 170° before and after the experiment, so that any ammoniacal vapors contained in it may be driven over to B.

By weighing the tube B after the whole of the volatile alkali has been taken up, the increase of weight will show the quantity of ammonia produced, and from this the nitrogen is found, for seventeen parts by weight of the dry ammoniacal gas represent fourteen of nitrogen.

Having, by one or other of these processes, arrived at the knowledge of the quantity of carbon, hydrogen, and nitrogen contained in the fuel, the oxygen, if any, will be the difference between the combined weight of the three, and that of the entire organic or combustible matter. Sometimes, however, it is necessary to consider the sulphur in the analysis of coals, when this element is present in appreciable quantity; because, during the combustion of the substance in the air, it becomes oxidized, and passes off with the carbonic acid and water as sulphurous acid. Its quantity may

be determined by deflagrating a known weight of the coal with about two parts of nitre, and eight or ten of chloride of sodium, care being taken that both compounds be free from sulphuric acid; the sulphur is by this means oxidized into sulphuric acid, which becomes fixed by combining with the base of the nitre. By washing the mass with water, precipitating the acidified solution by chloride of barium, collecting the sulphate of baryta, and drying, burning, and weighing the latter, the quantity of sulphur may be calculated. About five-eighths of the portion of sulphur should be deducted from the oxygen or loss expressed in the foregoing, and the difference taken as the true value of the oxygen contained in the compound.

Although the ultimate analysis gives a comprehensive insight into the nature of a fuel, and likewise a means of finding its heating power theoretically; still it leaves much to be desired in practice to enable one to form a correct estimate of its actual heating effect in manufacturing operations. Many circumstances concur to render the amount of work which a given quantity of fuel will perform, less than theory indicates—the principal cause of the discrepancy being the want of such an arrangement of furnaces, as that the whole of the caloric should be directed to, and actually enter into, the performance of the work to be done. This is a desideratum which can scarcely be expected to be attained in so complete a manner as to yield practical results, agreeing exactly with calculations founded on the nature of the fuel; the closer, however, that one can approach to this standard the greater will be the economy realized, and the nearer will the practical results coincide with the deductions of theory.

To arrive at an exact knowledge of the actual quantity of heat which a fuel ought to produce by combustion is impossible, no means being at hand for insuring definiteness to the result; but when, as in the determination of the atomic equivalent of a body, an arbitrary standard is taken, and the quantity of heat which other bodies produce is estimated with relation to such a standard, a comparative measurement is arrived at, which, though not expressing the absolute amount of heat produced, serves all the requirements of the arts. The arbitrary standard assumed, is the quantity of the fuel required to raise the temperature of a given weight of water a certain number of degrees, or the quantity of water which a given weight of the fuel or combustible will raise one degree. This amount, whatever it may be, is taken as the unit of heating power, and the number of such units, or the fractions thereof, which an equal weight of any particular fuel indicates by experiment, is taken as the heating or calorific power of that combustible.

ESTIMATION OF HEATING POWER.—Several investigators have bestowed considerable attention upon the subject of the quantity of caloric developed by the combustion of different substances. LAVOISIER, LAPLACE, and RUMFORD, were the first to enter this field, and the research has been prosecuted with increasing success by several others, down to the recent investigations of DESPRETZ, DULONG, and ANDREWS. The

principle upon which one and all founded their experiments, was that of determining the effect produced upon a third body by the heat given out during the union of the combustible under examination with oxygen.

In the experiments of LAVOISIER and LAPLACE, the body employed for this purpose was pounded ice, which was so applied around a balloon as to intercept all the heat. Fig. 88 shows a section of their apparatus, which they termed a *calorimeter*. The heating power

Fig. 88.

was estimated in this case from the quantity of water produced by the melting of the ice, and which flowed into the receivers, as seen in the engraving. These philosophers determined the amount of heat requisite to melt one pound of ice, as being sufficient to raise the same weight of water at 32° to 135°, or 103 pounds of water one degree. The more accurate experiments of PREVOSTAYE, DESAINS, REGNAULT, and others, as stated in a preceding part of this article—Vol. II., page 20—have shown that the heat which melts one pound of ice is sufficient to raise an equal weight of water to 142°, or seven degrees higher than was estimated by LAPLACE and LAVOISIER.

A moment's consideration of this method will convince the reader that it was liable to lead to wrong results, because it was impossible to recover the whole of the water produced by the liquefaction of the ice. This is the principal reason why the numbers given by these original investigators are too low. RUMFORD substituted water for the ice, the increase of the temperature of which, after the absorption of the caloric, as indicated by a delicate thermometer, was taken as the measure of the heating power of the substance tested. Many improvements have been made on RUMFORD'S method, which is now generally followed in the prosecution of these inquiries. The heating value of any substance is estimated from the number of pounds or parts of a pound of water, which one pound weight of the substance to be tried will

raise one degree of Fahrenheit. The following table shows the results arrived at by different experimenters:—

Name of Combustible.	Symbol.	Symbol of product of combustion.	Pounds of water raised 1° by one pound of substance or units of heat.	Pounds of water raised 1° when one pound of oxygen combines with the combustible.	Authorities.

The fifth column in the preceding table has been given, as having reference to a law propounded by WELTER, namely, that all combustible bodies disengage the same amount of heat during their combination with the same weight of oxygen; or, in other words, that the caloric developed was proportionate to the amount of oxygen assimilated during the combustion. WELTER founded this theory upon the results of LAPLACE, LAVOISIER, DESPRETZ, RUMFORD, and others, which must be admitted to be less trustworthy than those obtained by DULONG, GRASSI, ANDREWS, and other modern investigators; and it will be seen that when the numbers of the latter are adopted, the relation sought to be established does not hold good. To give one instance: hydrogen combines exactly with three times the quantity of oxygen that carbon takes up, and so from WELTER's theory the heat developed should be three times greater when hydrogen is burned, than when an equal weight of pure carbon is subjected to the same process; but from the results of the last-mentioned chemists, the ratio is between one to four and one to five. This wide difference is only observable, however, with combustibles very dissimilar in their nature, for when they approach to identity in physical appearance, as wood, peat, and coal, the estimation of the oxygen taken up gives an average indication of the heating power of the substance, which, without being absolutely correct, will answer most purposes.

BERTHIER has founded a system of analysis upon this theory, by which the oxygen is estimated, and therefrom the heating power of the fuel deduced. It is easy and expeditious, and may, under the foregoing circumstances, be occasionally adopted. He mixes a weighed portion of the finely-powdered fuel with thirty to forty times its weight of oxide of lead—litharge—and introduces the compound into a fireclay crucible, pressing it gently, and covering the whole with a thick layer of the litharge. The crucible is then carefully closed, and placed on the fire, where it is gently heated till the whole of the carbon and hydrogen is burned. During this process, the mass, being semifluid, is considerably distended by the carbonic acid and water, resulting from the combination of the elements of the fuel with the oxygen of the metallic oxide; towards the end of the operation, therefore, the fire should be quickened, and as soon as the crucible has attained a bright redness, it should be taken out, and its bottom struck gently against a stone or piece of iron, so as to cause the particles of reduced metal to accumulate and form a button. As soon as cold the crucible is broken,

and the metal, coated with oxide of lead and slags from the ashes of the fuel, is abstracted. It is cleaned from the adhering impurities by a few blows of a hammer upon the anvil, and subsequent brushing, after which it is weighed. From the number thus found, the oxygen required for the combustion of the fuel is calculated, since it is derived from the oxide of lead—a definite compound of equivalent proportions of lead and oxygen. When pure carbon is operated upon in this way, it has been found that about thirty-four and a half times the weight of the sample of metallic lead has been obtained. This amount of metal stands in a definite relation to the oxygen entering into the combustion, and, consequently, according to the law propounded, to the heating power of the fuel also; for, supposing a certain weight of metal to be produced, the following ratio will give the heating power of the fuel: namely, as the metal obtained when operating with pure charcoal is to that reduced by the substance under experiment, so is the number expressing the units of heat of carbon to that of the fuel. For instance, the weight of metal obtained with pure charcoal is 34·5; allowing that with the subject of the experiment to be twenty; and taking ANDREWS' determination, or seven thousand nine hundred, to represent the heating power of the charcoal, while x represents the unknown heating power of the fuel; then,—

$$34\cdot5 : 20 :: 7900 : x.$$

$$\text{Or, the heating power } x = \frac{20 \times 7900}{34\cdot5} = 4580$$

nearly. If in a substance of a complex nature, such as wood, peat, coal, *et cetera*, the hydrogen and oxygen are in such a ratio as to form water by their combination, it is evident that the average result of the lead assay will approximate to the truth; but where this is not the case, and a quantity of hydrogen is present without oxygen to combine with it, the accuracy of the experiment is less to be depended on, because the heating equivalent of the former element is taken as if it were carbon, whereas it is shown by the foregoing table to be much higher. When great exactness is required, it is evident that the heating power must be determined from the elementary analysis of the substance and the estimated calorific power of the constituents. This may be done with considerable accuracy, since it does not alter the amount of heat developed, whether the combustion be effected under the influence of a concentrated stream of oxygen gas, or in ordinary

air. The method of performing the calculation is very simple. Supposing the elementary composition of the fuel examined to be as follows:—

	Per cent.
Carbon,	86.48
Hydrogen,	3.04
Oxygen,	7.10
Ashes,	3.38
	100.00

it would be necessary to deduct from these numbers the oxygen, and the equivalent of hydrogen which combines with it, and to account as available for raising the temperature only the remaining hydrogen and carbon. In the above analysis the equivalent of hydrogen which will unite with the oxygen of the substance, will

be $\frac{7.10}{8} = 0.8875$, which, when deducted from 3.04,

leaves 2.1525 as the weight of hydrogen which goes to generate heat. According to ANDREWS' numbers in the foregoing table, the units of heat which this

would produce may be expressed thus: $\frac{2.1525}{100} \times 33808 = 727.7$, and in like manner the carbon may

be valued, $\frac{86.48}{100} \times 7900 = 6833.9$; making together

$727.7 + 6833.9 = 7559.6$ as the heating power of the fuel. In the same way may the value of any other kind of fuel be found.

Having the expression of the units of heat generated, it is easy to find the thermometric temperature which it produces; to do this, however, involves the necessity of knowing the quantity of air required for consuming the matter, and likewise the specific heat of the products. It is well known that air is composed of seventy-seven parts of nitrogen and twenty-three of oxygen, of which constituents only the latter is available in combustion. Having a knowledge of the proportionate quantity of oxygen required to burn the combustible elements, the volume of air containing this proportion may be readily found. Thus, every part of carbon combines with 2.66 of oxygen, which is yielded by 11.59 of atmospheric air; upon similar grounds, the air required for the combustion of hydrogen is 34.78 parts. In both cases, the products are carbonic acid, water, and nitrogen, the weight of which may be ascertained from the data given. Now the heat produced by the combinations of these distributes itself among the gases, so that they all indicate the same temperature, and which can be estimated, since the specific heat of these bodies is known. The number thus obtained, and which represents the temperature of combustion, varies, however, with the nature of the fuel; and still, owing, perhaps, to the specific heat of the gases at a high temperature, the results should be viewed only as an approximation.

As an example of the calculation of the pyrometrical heating power of a fuel, that already submitted may be again taken. It has been shown that the absolute heating effect of this specimen is 7559.6 units of heat, and that 0.8875 of the hydrogen contained in it is taken up by the oxygen, leaving 2.1525 of that element to undergo combustion with extraneous oxygen. It has been likewise stated that 11.59 parts of atmo-

spheric air are required for the complete combustion of one of carbon, and, upon the same grounds, that hydrogen requires 34.78; hence the weight of air required to convert the carbon and hydrogen of the fuel into carbonic acid and water would be—

$11.59 \times 86.48 = 1002.3$ parts for the carbon, and
 $34.78 \times 2.1525 = 74.8$ „ hydrogen;

making a total of 1077.1.

From these } 326.5 parts of carbonic acid,
 are produced }

19.37 „ water, and

819.88 „ nitrogen, to which it

is necessary to } 8.00 „ water, formed by the
 add }

union of the oxygen of the fuel with a portion of its hydrogen; thus making a total of $27.37 = 19.37 + 8.0$ parts of water. The specific heat of carbonic acid being 0.221, the amount of caloric required to raise 326.5 parts 1° would be $326.5 \times 0.221 = 62.16^\circ$

The specific heat of aque- } $27.37 \times .847 = 23.18^\circ$
 ous vapor is 0.847; hence, }
 the coefficient for nitro- } $819.88 \times 0.273 = 223.80^\circ$
 gen is 0.273; therefore, }

309.14

This number expresses the total amount of heat carried off by the products of the combustion of one hundred parts of the fuel; hence,

$$7559.6 \div \frac{309.14}{100} \text{ or } \frac{7559.6 \times 100}{309.14} = 2445.3;$$

which number represents the thermometrical heating effect of one part. In this calculation the specific heat of the ash has not been taken into account; but the quantity of caloric lost in this way is so insignificant, that the results are but very slightly affected by it.

Pursuing the same course, the pyrometrical heating effect of any other kind of fuel or combustible, however numerous its ingredients, may be ascertained; that is, by finding the absolute heating power by the formula already given for the purpose, and dividing it by the sum of the specific heat of the products multiplied by their total weight, the quotient will be the available heat for any particular work when the fuel is burned.

It may here be remarked, that when a fuel is consumed in oxygen gas, the pyrometrical effect is much greater than when the combustion takes place in ordinary air, although the units of heat are the same in both cases. The difference of effect arises from the fact, that the nitrogen of the air passing through the fire in considerable quantities, renders latent a large amount of heat—the difference between the indication in oxygen and air.

The following table shows the heating effect of a few combustibles, as well when burned in oxygen gas as in air, calculated according to the above formula:—

Pyrometrical Heating Power.			
Name.	Symbol.	In Oxygen.	In Atmospheric Air.
Carbon,	C	9753°	2450°
Carbide of hydrogen,	C H	4944	2286
Ether,	C ₄ H ₆ O	4035	2070

It is assumed that the whole of the combustibles named in this table are consumed, but in practice this never happens; hence, the heating effects given are higher than would be found to result when performing actual service; further, it is taken for granted that the combustion takes place in the shortest possible period of time, and that whilst it lasts, an equal amount of caloric is evolved each instant, a condition never fulfilled in the furnace. The discrepancy produced by both these sources of error, between the practical results and theoretical calculations, is to some extent

counteracted by the high temperature required to commence the combustion.

Having alluded to the process published by BERTHIER for the determination of the heating power of a fuel, the following tables are submitted as the results of his investigation; and although it will appear from what has been said in reference to WELTER's theory, that these results, from being founded upon it, are not quite correct, yet they may be useful as a close approximation to the pyrometric values of the substances mentioned:—

I.—WOOD.

Species of Wood.	Dried in the ordinary manner. Berthier.		Containing nine per cent. of water. Winkler.		Perfectly dried. Schodler and Peterson.		
	Pounds of lead reduced by one pound of wood.	Pounds of water which one pound can heat from 32° to 212°.	Pounds of lead reduced by one pound of wood.	Pounds of water heated from 32° to 212° by one pound of wood.	Pounds or oxygen required for the complete combustion of one pound of wood.	Pounds of water heated from 32° to 212° by one pound.	Air at 66° Fahr. required to consume one pound of wood.

The numbers cited in some of the preceding tables, as indicating the heating power of many kinds of fuel, appear at first sight contradictory to the known results obtained with such materials in the furnace. Thus considerably more heat is produced, judging from the work performed, when hard woods are burned than with the softer varieties; but numbers stated in the tables assign the greater heating power to the softer woods. SCHÖDLER and PETERSEN account for this apparent inconsistency by the difference in the amount of hydrogen producing unequal intensity of combustion in the two cases. They show that whilst woody fibre contains oxygen and hydrogen in the proportion in which they unite in water—that is, in the ratio of eight to one—all woods have the hydrogen in greater or less excess of the oxygen, and this excess acting at the temperature of combustion upon the carbon of the substance, produces a quantity of hydrocarbon gases, which are rapidly consumed. The residuary charcoal becomes in this case more porous, and, therefore, presents a larger surface to the oxygen of the air; the consequence of which is, that it is much more speedily consumed than if it remained a dense compact body. Hard woods have less hydrogen than the soft ones, and this fact accounts for the difference in the amount of heat produced. The annexed table gives the excess in one thousand parts after the oxygen has been assimilated:—

	Excess of hydrogen.
Ash,.....	5.05
Oak-wood,.....	5.08
Beech-wood,.....	6.50
Willow,.....	7.00
Birch,.....	7.50

Maple,.....	8.30
Pine-wood,.....	8.80
Deal,.....	9.50
Elm,.....	10.00
Lime-wood,.....	13.90

In the other tables above given, it will be seen that the highest place is assigned to lime-wood in point of heating power; but, in practical application, the oak produces a better result. The difference of the time required for the combustion of the two accounts for the inequality. In the case of lime-wood, a considerable quantity of its carbon is taken up by the large excess of hydrogen, and is given off in the shape of inflammable gas, which presents an extended surface to the oxygen, and is consequently speedily consumed; the residuary charcoal burns rapidly on account of its porous nature, arising from the evolution of the particles of hydrogen and carbon. Now, oak-wood not having so large a per centage of hydrogen to react upon its carbon, of course a greater weight of the latter remains, and this being denser than in the case of lime-wood, a

less surface is undergoing combustion in the fire, and a longer time will be occupied in its burning. It rarely happens that the arrangements for the application of caloric in the arts are of such a nature as to allow of the entire economization of the heat produced, more especially when it is developed intensely and in a short space of time; hence, when soft woods are employed as fuel, there is a considerable amount of heat lost, by which the working effect is lessened. On the contrary, with woods which burn slowly, the loss is not so great, since it is nearly wholly absorbed in proportion as it is developed by the combustion. The same remark applies to coals; and this is the reason why particular kinds are employed for steam-generating purposes, for glass and porcelain works, *et cetera*; but although there appears a very great difference arising from this cause, yet it does not follow that the pyrometric effect of the one is less than that of the other. If, for instance, two equal weights of oak-wood be consumed—one in the form of chips or shavings, and the other in a compact mass—it will be seen that the former will burn in a much shorter period than the latter, and that the practical heating effect produced by the one will be much less than by the other. It is evident that the pyrometric heat is the same in both, only that the evolution of caloric from the divided portion is so rapid as to cause the dissipation of a large part of it. Where a high temperature is necessary, it is evident that a fuel capable of giving off its caloric in a comparatively short space of time is required; and hence the preference given to soft wood, or finely cleft hard wood, in the glass furnace and porcelain kiln. The facility which minute division affords for rapidity of combustion has, however, its limit, which, when exceeded, instead of expediting, retards, and when carried to extremes, actually arrests combustion entirely, as may be observed with coal, coke, wood, and peat charcoal, when crushed to a powder. In this case the air has no access to the combustible except at the surface, so that the area of contact is very limited when compared to the bulk, and, consequently, ignition is arrested. When it happens that fuel in this minutely divided state is the only kind available, the combustion is assisted by piling blocks of limestone, sandstone, or other material upon the grate, and placing the fuel—such as sawdust, slack, bres, *et cetera*—upon them, in which case the currents, ascending through the interstices, supply the requisite oxygen to the fuel. If the grate does not admit of this arrangement, the finely-divided combustible is converted into a valuable compact fuel by blending it with tar, pitch, or some such binding material, as described under Patent Fuels.

In consequence of the defective furnace arrangements in most manufacturing establishments, the quantity of heat absorbed and utilized bears, in general, no definite relation to the quantity produced, without taking into account the proportion of the fuel, which is either not at all, or only partially burned. The loss from these two causes alone has been estimated to be equivalent to the one-half of the coals consumed under the imperfect systems generally followed. Of late years considerable attention has been directed to discover some means whereby the cause of the first loss might be

removed by an improved construction of the furnaces or fire-places, with a view to their better retention of the heat, and marked benefits have arisen to many branches of trade, but more especially to those making extensive use of steam, from the various investigations instituted. Although the waste of caloric from both the causes mentioned—namely, the non-retention of the heat and the imperfect combustion of the material—is very great; yet a considerable waste of fuel is occasioned by other circumstances which attend ordinary combustion, and which require investigation as much as the others. To enter into a minute discussion of all these would be tedious; but a short examination of the principal ones will be necessary, to point out the sources of the difference between the calculated value of fuel in heating power, estimated from experiments controlled in such a way as is not possible when the materials are burned in the ordinary furnace or grate, and that which results in practical operation.

In the first place, it will be evident that the mere maintaining of a fuel in a state of combustion, whether in a grate or furnace, involves, and is dependent upon, a certain loss of caloric, as well latent as sensible, in the production and expansion of the gases resulting from the change, whereby they ascend from the substance and admit the fresh air to keep up the chemical action. It is well known that, under the provision made for burning fuel of any description, the air which is admitted must always be greater than the amount which theory assigns as sufficient, otherwise the combustion would be imperfect, and a heavy loss sustained. Admitting, however, that no more than is absolutely necessary passes through the fire, it will be seen, on reflection, that still a great amount of heat is rendered useless by the draught in the chimney. From the tables already given, it appears that for the complete combustion of one pound of dry wood an average of 5.94, or in whole numbers, six pounds weight of air at 32°—equal one hundred and forty-eight cubic feet—are required. Admitting that this volume of gaseous matter passes off from the fire to the chimney at a temperature of 300°, the whole heat lost will be $1620^\circ - (6 \times 270) = 06$, or six per cent. It seldom happens, however, that the temperature of the escaping gases is so low as that assumed in this instance; and where their heat is greater, of course, the loss will be proportionally increased; and the same effect will follow when the quantity of air passing through the furnace is greater than the theoretical amount.

Another cause of the reduction of the heat, and the prevention of a due effect resulting from combustion in the furnace, is the water which is usually present in fuels in greater or less abundance. The loss suffered from this alone is twofold: firstly, inasmuch as the amount of real combustible is diminished by it, whe-

ther it be large or small; and, secondly, because by its conversion into steam, in which state it passes off with the products of combustion, it unites with a large amount of caloric, which becomes latent.

When the proportion of water is appreciable, the quantity of caloric which is given off is very great. Wood, for instance, contains, after being dried in air, about one-fifth of its weight of moisture, so that when employed in this state as a fuel, only four-fifths of the weight taken is capable of generating heat. Supposing that 40.6 pounds of water are heated from 32° to 212° by one pound of wood perfectly free from moisture, it is evident that only 32.5 pounds would be brought to the same degree by the available fuel in the pound of common air-dried wood. Further, the one-fifth of moisture is expelled in steam, and this takes up as much caloric as would bring 5.5 pounds of water from the freezing to the boiling point. Founding a calculation upon this fact, the one-fifth of a pound of water present would assimilate as much heat as would raise 1.1 pound of water to the boiling point. By adding both, the total loss will be $9.2 - 8.1 + 1.1 = 22.5$ per cent. less than if dry wood were employed. This example shows, in a striking manner, the great advantages which the employment of wood, peat, lignite, or such fuel as is liable to be more or less saturated with hygroscopic matter affords, when they are thoroughly exsiccated, over the same when containing ten, fifteen, or twenty per cent. of moisture. Where wood is much employed, care is taken to submit it to a preliminary drying operation, so that its combustion may be rapid, and that the loss described may be avoided.

It may be remarked, however, that water does not, under all circumstances, diminish the calorific effect of a fuel; but on the contrary, when judiciously managed, adds to it in a high degree. BUNSEN and FYFE have shown that aqueous vapor passed over incandescent fuel suffers decomposition; its oxygen is abstracted by the highly heated carbon, and carbonic oxide results, while the hydrogen passes off partly uncombined, and partly associated as carbide of hydrogen. These three products in the presence of sufficient oxygen, and the high temperature of the furnace, are capable of undergoing further combustion, and yield a large amount of heat by being converted into carbonic acid and water. In numerous experiments it was shown that the caloric developed in this manner, more than compensated for the fuel employed in producing the gases. The application of aqueous vapor, however, demands caution; for when used in too great an excess, it reduces, rather than increases the temperature of the fire. Its effect is to diminish the heat, unless used sparingly, and with a free admission of air to promote the combustion of the inflammable gases.

The method in which water is utilized for raising the temperature, is to place a vessel of this liquid beneath the bars, so that the heat radiated downwards may have the effect of producing the steam without further trouble; where steam-engines are employed, a jet of the waste vapor is allowed to issue under the furnace. A mistaken inference from this fact leads many to moisten the coals before throwing them on the fire,

with a view to the increase of the heat; but that the contrary effect is produced, is evident from what has been already detailed; the water in this case serves only to slacken the combustion, and render a considerable amount of heat latent. It is the practice, especially, to moisten small coals and slack, when it is required to burn them on the furnace bars, and in this case the loss in heat from the presence of the water may to a certain extent be compensated by the advantage of the adhesion produced between the particles of the fuel, whereby it is prevented from falling into the ash or stoke-hole. Clay, plaster, or bituminous substances would serve better.

Besides the loss of caloric which results from the gases or products of combustion passing in a superheated state into the chimney, as well as from the presence of an excess of moisture, there is another source of loss which is of far greater importance, and which is much more generally felt. It is necessary for keeping up the ignition that the column of air in the chimney be expanded by heat, and thus rendered specifically lighter than the surrounding atmosphere, to produce a constant current through the fire. The moisture in a fuel may be removed by a preliminary desiccation, the extent of the heat-absorbing surface may, under certain circumstances, be augmented, so as to arrest and economize a large amount of caloric which might otherwise be lost; but to effect a complete combustion of the fuel, with the least possible volume of air, demands a thorough knowledge of the scientific principles involved in this change, as well as of the products resulting therefrom, together with the strictest attention on the part of the *stoker*. It is evident that a definite relation must exist between the weight of combustible elements in a fuel, and the oxygen which is required to convert these into carbonic acid and water, and that to effect the latter change within the limits of this relation requires the most favorable circumstances, such as properly arranged furnaces, the adjustment of the fuel and draught of air passing through the fire, with skill and constant attention on the part of the fireman.

In a grate of any given dimensions, and burning a given weight of fuel in a determinate period, the quantity of air to be supplied can be easily deduced with the aid of known experimental results, as well as from theoretical calculations. Thus, according to the determinations and analyses quoted at page 112, one pound of peat requires for complete combustion from seventy to one hundred and thirty-four cubic feet of air at 66.2°; medium kinds of this fuel, one hundred and forty-nine cubic feet; one pound of peat charcoal requires one hundred and fifty-five to two hundred and twenty-eight cubic feet; one pound of brown coal, according to the lead test, one hundred and thirty-nine to two hundred and twenty-two cubic feet, and by analysis, one hundred and sixty to two hundred and forty-eight; one pound of coal requires, by the lead test, one hundred and seventy to two hundred and seventy-nine, average qualities two hundred and twenty-eight cubic feet; according to RICHARDSON'S analysis, from two hundred and forty-eight to three hundred and three; by REGNAULT'S, average qualities, from the coal formation, take three hundred and twenty to three hundred and

thirty-two—those from the secondary formation, two hundred and ninety-three to three hundred and twenty-six cubic feet; one pound of coke requires one hundred and ninety-four to two hundred and fifty cubic feet; one pound of anthracite, according to the lead experiment, demands two hundred and thirty-three to two hundred and seventy-seven—according to REGNAULT'S analysis, three hundred and twelve cubic feet. A cubic foot of air weighs 0.03794 pound Hessian—0.07500 English—at the above temperature.—*Richardson and Ronalds*.

Now, in these calculations, it is presumed that the oxygen of the air is in contact with every particle of the fuel during ignition. Could the same condition be insured in the furnace, it is evident that the great desideratum required in combustion would be attained; no escape of combustible gas could then ensue, nor of the carbonaceous particles which give to the gases passing up the chimney the character of smoke; and the greatest possible heat arising from the burning of the substance in air would be developed. Indeed, nothing would be wanting to extract from the fuel the benefit of its total theoretical heating power, but such an arrangement of the furnace as would perfectly utilize the caloric so produced. No one, however, who has any experience as to the manner in which the fire is managed in the ordinary kinds of furnaces, will hesitate to assert that the above conditions are never supplied. The coals are thrown in thick layers upon the grate, by which the existing temperature for a time is greatly depressed, being absorbed in part by the cold fuel, and by the dispersion of its hygroscopic matter. In addition to the reduction of the heat temporarily, the thick bed of fuel impedes the draught, and sufficient air cannot enter to effect a consumption of coals, adequate to the generation of the amount of heat required. The portion of air which traverses the fire is deoxidized by the ignited fuel on the bars, and no oxygen, for a considerable period, can come into contact with the mass lying upon that which is burning; but although in this way it does not contribute to the pyrometrical effect, the temperature of the ignited mass, and the heated gases permeating it from below, cause a distillatory change, by which the whole of the available hydrogen, together with a large percentage of the carbon, is expelled as hydrocarbon gases, which escape combustion. This decomposition, occasioned by the undue fuelling, does not only waste the combustible matter in the way alluded to, but it diminishes the heat which is produced by the portion that burns, since the gases in passing off carry with them a considerable portion of caloric as latent and sensible heat. Further, after the distillation of the gaseous matter is effected, and the residuary coke has acquired incandescence, an additional loss is sustained in consequence of the carbonic acid in which the combustion of the carbon in the base of the fire terminates, being, by the deoxidizing power of the overlying glowing combustible, transformed into carbonic oxide, the abstracted oxygen taking as much again of the carbon as it would do if perfect combustion had occurred. The double volume of gas produced under these circumstances renders a large quantity of heat ineffectual for useful application.

It is thus that three radical and distinct sources of loss arise out of the profligate system of stoking usually practised; namely, waste of the volatile inflammable hydrocarbon gases of the substance; loss of the fixed carbon by the deoxidation of the carbonic acid; and, lastly, loss of the caloric with which the combustible and non-combustible gases combine and carry off, as well in the state of latent as of sensible heat.

Independently of such gross waste in the application of fuel, another of no little moment exists—namely, the rapidity of the draught in the flues. Experiments have shown that in those cases where the flue has been lengthened with the view of affording a greater heating surface, the effect produced was materially affected by having the damper entirely withdrawn, or only partially so. Such a result is a natural one, considering the imperfect conducting power of air, and also of water, when it is on the point of passing into the state of elastic vapor; for the one does not transmit the caloric to the fluid, nor does the latter combine with it so readily as to sufficiently abstract this principle from the gases when they rapidly circulate around the boiler and pass away. URE illustrates this non-conducting quality of gases passing rapidly over a conducting surface by the slight elevation of temperature which is experienced in guns, cannon, *et cetera*, notwithstanding that the temperature produced by the combustion of the powder is very high. The reason is, that the rapid evolution of the gases prevents the absorption of the caloric by the metal. In the case of a furnace, the barrel of the gun may be represented by the flue; the force of the explosion, and the products therefrom, by the draught and vapors produced in an ordinary furnace; and the effect of non-absorption in the latter instance, will be as marked as in the former if the draught be too great. Hence it will be readily inferred, that to absorb the whole or the greater part of caloric, time must form an important consideration to afford a more or less prolonged contact of the heated gases with the material of the boiler; consequently, where the draught is increased rather than checked within proper limits, the pyrometrical effect is, to a considerable extent, lost.

The causes of these losses in the production of heating effect, and, consequently, of mechanical power, have of late years engaged much attention, as well in America as in this country; and although the investigations, which have been conducted with a view to ascertain the conditions by which the largest amount of work might be performed by the fuel, have added materially to the knowledge of those circumstances that affect the heating power, they have scarcely touched upon those which relate to the economizing of fuel. Several modifications of furnaces have been patented of late years for the prevention of smoke, while, at the same time, it is alleged that the heat of the fire is increased; but it is to be feared that many of these arrangements, while ostensibly obviating one evil, produce others quite as injurious. This arises for the most part from the injudicious introduction of cold air at a part where the temperature is too low to cause combustion of the inflammable vapors and portions of carbon; or the quantity of air admitted is too great, and

the heat rendered latent by it amounts to as much or perhaps more than in the ordinary fire. Much benefit will doubtless accrue from those improvements in the furnace by which the supply of fuel upon the grate is regulated, and rendered more or less independent of the stoker. By these the loss arising from imperfect combustion, as already explained, is to a great degree avoided. To enter into a discussion and notice of the several improvements would be, in some degree, foreign to the subject of this article; but the reader who may be desirous of information on this matter, is referred to a work by Mr. W. WYE WILLIAMS, to the *Dictionnaire des Arts et de Manufactures*, published by LABOULAYE, and to KNAPP, RONALDS, and RICHARDSON on *Fuel*.

Regarding the investigations above alluded to, the chief object with which they were undertaken was to find the best coal for steam navigation. As already mentioned, there are many kinds of coal, which, though capable of producing a high temperature during combustion, yet are not economical for the purposes of the navy or other boiler furnaces. The reasons have been already stated. To find the best among the numerous varieties of coal extracted even from the same pits, and still more from different fields, the Government of the United States intrusted Professor W. R. JOHNSON with the investigation. This example was soon followed by Great Britain, whose manufacturing and naval interests, depending so much on steam, rendered such an inquiry most urgent. Dr. LYON PLAYFAIR and Sir HENRY DE LA BECHE were appointed as the principals in this research. In both the American and British investigations, the experiments were made with reference to the following principles:—

Firstly. The fuel should burn so that steam may be raised in a short period, if this be desired; in other words, it should be able to produce a quick action.

Secondly. It should possess high evaporating power—that is, be capable of converting much water into steam with a small consumption of coal.

Thirdly. It should not be bituminous, lest so much smoke be generated as to betray the position of vessels of war when it is desirable that this should be concealed.

Fourthly. It should possess considerable cohesion of its particles, so that it may not be broken into small fragments by the constant attrition which it may experience in the ship.

Fifthly. It should combine a considerable density with such mechanical structure that it may be easily stowed away into small space—a condition which, in coals of equal evaporative values, often involves a difference of more than twenty per cent.

Sixthly. It should be free from any considerable quantity of sulphur, and it should not progressively decay, both of which circumstances render it liable to spontaneous combustion.

The boiler employed by JOHNSON in his trials of the evaporating power of coals, was thirty feet long, and three and a half in diameter; this was set over a furnace, and the heated gases, after passing through two interior return flues, each one foot in diameter, escaped by the side flues exterior to the boiler to the chimney, making the entire length of circuit for

the products of combustion one hundred and twenty-one feet. The grate surface was sixteen feet and a quarter, and the area of heat-absorbing surface three hundred and seventy-seven and a half square feet, so that the ratio of both surfaces was as one to 23·2. The chimney was sixty-three feet high, and had a cross section of three hundred and twenty-four square inches.

On the other hand, a Cornish boiler was employed in the English investigation, the length of which was twelve feet, with an external diameter of four feet. The furnace, as usual with this class of steam boilers, was constructed in a flue two feet in diameter passing through the middle of the vessel. After the products of combustion traversed the central flue, they returned by two other external side ones to the front, and thence entered a main under the boiler, and which led to the chimney, thus making a course of thirty-six feet. A grate five feet square was employed, and the absorbing surface amounted to 197·6 square feet, so that the latter was to that of the fire as 1 to 39·5. In this case the height of the chimney was 35·5 feet, and its cross section presented an area of 182·25 square inches.

The amount of coals consumed in the hundred and forty-four trials made by JOHNSON at Washington was sixty-two and a half tons; and, in the eighty-two experiments conducted at London by PLAYFAIR and DE LA BECHE, about fourteen tons six hundred. The average weight of coals burned in the American inquiry at once was eight hundred two quarters twenty-six pounds, and in the English, three hundred two quarters.

The results of these experiments were published by Professor JOHNSON in a Report to Congress in 1844, and by Sir HENRY DE LA BECHE and DR. LYON

PLAYFAIR in a series of Reports to the British Government, concluded in 1851; but the relation between the composition of the coal, as ascertained by analysis, and its value for producing steam, is not by any means very clearly brought out even by these experiments. They prove, indeed, by the very differences which they exhibit, as compared with the results of experience, that the only trustworthy method of determining the value of a fuel, especially for steam purposes, is that of practical experiment under the boiler, where several tons and not pounds are consumed. It appears, therefore, to be unnecessary to transcribe the voluminous and elaborate tables embraced in the American and English reports, which the few readers who may be desirous to inspect them will find in RONALDS and RICHARDSON'S *Chemical Technology*. It may be stated, however, that in JOHNSON'S experiments the weight of water evaporated at 212° from one cubic foot of coal was found to vary from 440·8 to 556·1 pounds with different specimens of anthracite; from 350·2 to 478·7, with bituminous coking coal; and from 353·8 with Scotch, to 439·6 with English bituminous coal. In the English experiments, the Newcastle coal varies from 325·24 to 529·34; and Scotch coals from 352·58 to 460·82. The following may be given as a summary of the latter series of experiments, where A represents the evaporating power, or number of pounds of water evaporated at and above 212° by one pound of coal; B, rate of evaporation, or number of pounds evaporated per hour; C, weight in pounds of one cubic foot of coal, as used for fuel; D, space occupied by one ton in cubic feet; E, results obtained in experiments on cohesive power of coals, or, in other words, the per centage of large coals; and F, the per centage amount of sulphur contained in the coals:—

The volume of the coals with reference to their respective qualities as a solid compact fuel was tested by JOHNSON, in the state in which they come to market, but in the English inquiry the several varieties were broken up into fragments not exceeding one pound in weight; hence the results in the latter were necessarily more uniform than in the former, and, therefore, the quantity of steam raised by equal bulks of the coal would from this, if from no other circumstance, be in favor of the English coals. Where the specific bulk of a fuel becomes a matter of consideration, as it must do when required for shipping, attention should be devoted to the size of the lumps, for even with the same coal there is great difference in the weights of two given volumes, one of which is in large and the other in smaller pieces.

The moisture present in the British coals was not deducted in calculating their evaporative value, as it was considered of greater practical importance to esti-

mate this in the state in which they were found in the market.

The British commission, besides employing the direct practical method—that of burning a portion of the coal under the boiler—had recourse for the calculation of the value of the fuel to the lead test, as also to the ultimate analysis. Between the results of these three methods there is often to be found in their tables a considerable difference, amounting even to a virtual contradiction. This has been shown to arise from the almost utter impossibility of economizing the heat under the boiler in the practical test, and from the fact of the oxygen derived from the litharge being made the basis for calculating the pyrometrical effect of the fuel in the lead test, an assumption that has been shown to be erroneous.

It is at least certain that very different quantities of steam were found to be raised by coals capable of reducing the same amount of lead, and hence it is evi-

dent that the lead test cannot be relied on as an exact measure of the value of a fuel, although it may afford an approximation. The same observation applies to the method of testing by the estimation of the coke or fixed carbon, the amount of which does not present a sure guide in the determination of the value of coal, since a wide difference was found between the steam generated or work done by different coals possessing an equal average amount of carbon.

With respect to the value which ought to be attached to the experimental results obtained by actually burning a portion of coals under the boiler, the information which even this method affords for practical guidance is not so reliable as might appear at first sight. This arises from the circumstance, that the effect of the fire depends to a great extent on the form and setting of the boiler; and as marine boilers differ from the Cornish ones in these particulars, the numbers found in the course of the experimental investigation do not present the actual equivalent of work to be expected in steamships. Even from the smallness of the boiler employed in the experiments, the results fell short by twenty per cent. of the maximum amount of work which the same fuels could perform when applied to larger boilers constructed and set on the same principles. The inquiry is rendered less efficient from another cause, namely, the want of a thorough control and measurement of the air passing through the furnace; for, doubtless, a knowledge of this would be of immense service in the application of fuel, so as to develop its entire pyrometrical effect under the most favorable circumstances.

The Editor concludes this article by acknowledging his obligations for much assistance to the very able work of RICHARDSON and RONALDS already referred to, as likewise to MILLER'S *Chemistry*, DUMAS' *Traité de Chimie Appliquée aux Arts*, and Dr. URE'S *Dictionary*.

GAS.—*Gas*, French; *Gaz*, German.—A recent writer appositely remarks, that in the present era, when the creative faculty of man seems to be more than ever busy in its obedience to the primitive injunction to subdue the earth, it seems but to be consistent with the harmony and order of the world that the production of light should have been one of the earliest aims of British industry. For the daily experience of social as well as of organic life, declares light to be one of the chief necessities of man, no less than of every other living thing; and sense and science alike at once accept as truth, that light was the first material force that worked in the embryo universe.

From the tallow dips of the last generation, powerless and void of everything save smell, to the bright stearic acid that cheers the drawing-room now-a-days, what a development! In the iron arteries under towns, in the constellations of burners that rule the nights of favored days, rising over the chaotic oil-lamps of old, what a creation! And can any one doubt that the same voice which first bade light to be, has summoned gas to the service of man, and pronounced the light from it to be good?

The discovery and earliest observation of elastic æriform fluids, capable of being inflamed and of imparting light and heat, must, according to HUGHES,

undoubtedly have been of great antiquity. The most ancient writings contain notices of inflammable vapors springing from fissures and cavities in the earth. It is evident, therefore, that gas being a natural production, no such individual as the discoverer and inventor of gas ever existed. Modern chemistry will have no difficulty in showing that all inflammable gases, whether arising naturally from rocks, or produced artificially by combustion or otherwise, are composed of simple elements, which present a remarkable analogy to the common bihydride of carbon, the gas chiefly consumed in our street lamps and houses at the present day.

Inflammable gas may be truly said to be as old as the first creation of organic matter, for wherever animal or vegetal substances have existed, by the immutable laws of nature they have been subject to eremacausis, and wherever decomposition has taken place, a variety of gases has been produced, some of them combustible, and others not. Whether the change be that engendered by the slow combustion of decay, or that more speedy process caused by the application of sensible heat, the effect is the same—the gases are equally produced in the two cases.

Gas may, in one sense, be called a more natural production than steam, although the latter has existed from the first creation of water, and in its palpable state, as proceeding from boiling water, must have been observed in all ages.

The *discoveries* of man in respect to gas and steam, ought rather to be called *applications*; they are conquests over the elements, the subjugation of great powers in nature to his use and convenience. So it is with nearly all great inventions, in which is found one power of nature after another, chained, confined, bound down, stored, and then let loose when required, and made to work machines, to propel ships across the ocean, to supply the place of human exertion itself in a thousand different ways; nay, to pass far beyond the actual powers of the combined labor of multitudes, and to effect that by a single effort which the manual strength of a world could scarcely accomplish.

If such astonishing applications of steam and gas had been made in the days of ancient Greece, what magnificent, expressive, and high-sounding names would have been found to convey their meaning! Instead of such contemptible little monosyllables as *gas* and *steam*, one might have heard of the spirit of coal and the spirit of water, with some superlative adjective to stamp the vast importance of each. In such an age these wonderful conquests would have thrown all meaner efforts into the shade; for them alone would poetry have strung its harp, and the grandest epic productions of genius might have commemorated the victory of man over the inanimate matter of nature, instead of dedicating her loftiest songs to the art of war.

As already stated, jets of flaming gases bursting out from the ground have attracted notice from a very early date, so that savage tribes, owing to the grandeur of the spectacle, apparently unsupported by fuel, considered the spots whence such emanated as the abodes of their gods. The well-known holy fires of Baku still burn, and are due to the ignition of light carbide of hydrogen with some naphtha vapor. They

are worshipped by the savages in the neighborhood of the Caspian Sea. In China, the borers for salt water often meet with streams of combustible gases, which they employ for illuminating factories and evaporating brines; consequently, the Chinese were acquainted with the use of coal-gas, long before the knowledge of its application was acquired by Europeans. The most familiar instance of the elimination of inflammable gases from the earth in this country, is the fire-damp of the miners; but it is not of such a good quality as that artificially produced.

Some of the earlier nations considered fire as a type of divinity, and one can scarcely wonder at the feelings of veneration occasioned by mysterious outbursts of flame, the origin of which appeared utterly incomprehensible. Hence superstition erected her altars over such flames, and claimed the interference of the gods to sustain the perpetual miracle. But all that had been observed with reference to inflammable vapors in olden times, was very far indeed from leading to any attempt to collect and use them. Their very nature and composition were unknown, and the most mistaken ideas prevailed as to their real elements. It was not until modern chemistry had exploded volumes of ancient dogmas, had traced the so-called elements to far simpler forms, and had taught the laws according to which simple bodies are combined in order to constitute all forms of matter—it was not till then that it began to be seen that the inflammable vapor of coal, wood, oils, and other fatty substances, was analogous with the marsh gas which arises in bubbles from the decomposition of vegetables under water; that it was of the same nature as the *ignis fatuus* or *Will-o'-the-wisp*, which on the wild moor or bog has lighted many a traveller to destruction; finally, that it was nearly the same as the gas which arises from the decomposition of water, however effected; and that, in fact, one of the constituents of water, the greatest antagonist and extinguisher of flame, was itself the most inflammable substance in nature, namely, hydrogen gas; while oxygen, the other element, is the greatest supporter of combustion.

Various opinions have been hazarded to account for the almost perpetual fires which were kept burning on the ancient altars. These are mentioned by STRABO and PLUTARCH, who add that when they happened to be extinguished, they were lighted by invisible means. The altar in the temple of Ægina may be mentioned as affording a good explanation of the mystery. Here a round hole, about thirteen inches in diameter, is observed in a block of stone. The circular orifice opens into a square one, which passes down through solid stone to a depth of several feet. The lower extremity of the square hole communicates with a cavity in which Mr. DODWELL supposes a fire to have been constantly kept burning, so that the flame did not appear above the surface of the fissure. He says, nothing more would be necessary than to pour oil into the orifice, when the flames would immediately burst forth, and appear to have a miraculous origin.—*Hughes*.

Although the application of the gases produced by the destructive distillation of pit-coal, as a means of obtaining artificial light, appertains to modern times, yet the germ of it may be traced back nearly two cen-

turies. In the year 1659, THOMAS SHIRLEY is said to have attributed the exhalations from the burning well of Wigan, in Lancashire, to the subjacent coal beds; and in 1664, the observation was made by Dr. CLAYTON, that combustible illuminating gas was formed during the decomposition of coal by heat, and that this could be collected.

One hundred years afterwards application was made of the fact, but by mere accident. In 1787, Lord DUNDONALD, of Culross Abbey, in Scotland, took out a patent for making coal-tar, and erected near the Abbey a series of ovens for this purpose. The tar was conducted by pipes from the condensers into cylinders of brickwork, each of which had a small opening at the top for the escape of the incondensable part of the products. To these openings the workmen were in the habit of attaching a cast-iron pipe by means of a mass of soft clay, and lighting the gas at the other end to give them light during the darkness. His lordship, also, was in the habit of burning the gas in the Abbey as a curiosity; and, for this purpose, he had a vessel constructed resembling a large tea-urn, which he frequently caused to be filled and carried up to the Abbey to light the hall with, especially when he had company with him.

But the true discoverer of the practical application of coal-gas for lighting purposes was Mr. MURDOCH, a Scotchman, who, in the year 1792, while at Redruth in Cornwall, made a series of experiments on the quantity and qualities of the gases produced by distillation from different mineral and vegetal substances. He was induced, by some observations which he had previously made on the burning of coal, to try the combustible properties of the gases produced from it, as well as from peat, wood, and other inflammable substances; and was struck with the great quantities of gas which they afforded, as well as with the brilliancy of the light, and the facilities of its production. He continued his experiments till 1798, when he removed from Cornwall to a situation of importance in BOULTON and WATT's works at Soho, and there he constructed an apparatus which, during many successive nights, was applied to the lighting of their principal building. In the meantime he tried various methods for washing and purifying the gas, and these experiments were continued with some interruptions till the peace of 1802, when a public display of the gas-light was made by him in the illumination of the manufactory at Soho on that occasion. He afterwards extended the same apparatus, so as to give light to all the principal shops in the neighborhood, where it was in regular use to the exclusion of other artificial light; and, finally, in 1808, he fitted up the gas apparatus in Messrs. PHILLIPS and LEE's cotton mill; from which time it gradually extended to all the cotton mills in the kingdom.

At the same time, much credit is due to Mr. WIN-SOR, who took out a patent for a similar process in 1806, delivered lectures on the subject, and endeavored to get up a joint-stock company for street-illumination. In this object he did not succeed till 1812, when some of the streets of London were first lighted with gas. Oil-gas was first prepared on a large scale by PHILIP

TAYLOR, who erected the gas-works at Paris soon after the peace of 1815.

NATURE OF ILLUMINATING GAS.—KNAPP justly remarks that the lighting properties of a gas, or mixture of gases, must depend upon the relation which the carbon in it bears to the hydrogen, and that it can only be turned to a useful purpose when there is more of the former of the two elements present than in fire-damp, and when the proportion of both approaches that of olefiant gas. Light carbide of hydrogen— CH_2 —contains 75.4 carbon to 24.6 hydrogen; olefiant gas— C_2H_2 —consists of 86 carbon to 12 hydrogen.

The illuminating power of different carbides of hydrogen varies considerably. Fire-damp contains one part by weight of hydrogen to three of carbon; but one part of hydrogen requires eight, and one part of carbon 2.666 parts of oxygen for combustion; now, supposing the oxygen of the air, which performs an important part in combustion, to combine with both simultaneously—then, as eight parts of oxygen consume one of hydrogen, just eight parts of oxygen would unite with the carbon, and consume three parts, or exactly the whole quantity. In olefiant gas, there is one part of hydrogen to six of carbon; therefore, under the same supposition, one part of hydrogen and three parts of carbon will be consumed together, whilst as much carbon, or three parts, will be set free. Although in reality the hydrogen is always consumed first, yet it is obvious that olefiant gas is capable, under similar circumstances, of supplying more carbon to the flame, and, consequently, of producing more light, and it would have a decided preference above all others, if it could be procured sufficiently cheap. This, however, is not the case, and one must be satisfied, from economical motives, with a mixture of gases, or, in other words, a compound gas, produced by the decomposition of certain substances of organic origin, and containing so much olefiant gas that it far exceeds carbide of hydrogen in illuminating power. When these organic substances are exposed to a certain temperature, the following process results. Certain volatile products escape, which partly condense on cooling into tar and aqueous fluid, whilst the rest is a mixture of gases, but contains likewise no small portion of the volatile vapors of different compounds, which remain dissolved in the cooled gases, without being condensed into liquids. A coaly residue which is termed *colce* is left.

The researches of numerous chemists upon coal tar, have led to the discovery of oily volatile products of very different chemical character, and which are chiefly carbides of hydrogen, with a very large proportion of carbon. To this class belong *anilin*, *leucolin*, *pyrrol*, *rosolic*, *brunolic*, and *carbolic acids*, and *naphthalin*. Most of these contain ninety per cent. of carbon, naphthalin as much as ninety-four; and in burning they deposit it in still greater quantity than olefiant gas. It is, therefore, easily conceived why the vapors of these substances remaining with the gas, so very much enhance its value. Such mixtures of gas and vapor are termed illuminating gas, without reference to the separation of noxious and useless impurities before it is used. Gas, consequently, is not a definite compound of light carbide of hydrogen or olefiant gas, but more

properly a mechanical mixture of very various bodies, some being only slightly or not at all luminous, whilst others are exceedingly so, as olefiant gas and the other carbides of hydrogen which possess similar properties, and to which the whole is indebted for its illuminating power. It is a remarkable circumstance, that carbon and hydrogen are capable of uniting in the same proportions by weight to form a series of gases and liquids, which only vary on account of the different amount of contraction of volume which their elements undergo in the moment of combination; and this alone can explain the great multiplicity of solid, liquid, and gaseous carbides of hydrogen which are known to exist.

It may be conceived that different substances, as wood, fat, and coal, must be suited in different degrees for the production of light-gas. Coal, fats, or oils, resin and tar, asphaltum, soap-water, and the refuse of animal bodies, are all practically employed, according to the locality, in the production of gas. The different nature of these bodies requires that different modes of preparing the gas from them should be adopted, and these will be considered separately further on.

The amount of gas from a given quantity of coal depends greatly upon its quality, and the manner in which its distillation is conducted; it is, therefore, very variable.

Experience has proved that English cannel is the best gas-coal, both as regards the quantity and quality of the gas which it yields. Scotch parrot coal comes next. Even the Berlin gas-works use cannel coal from England. In France, where cannel is not to be met with, highly caking coal of a similar character is selected, and on the East coast of England, caking coal is generally employed for the production of gas.

ACCUM found that one hundred cubic feet of coal gave from eighteen thousand seven hundred to nine thousand two hundred cubic feet of gas, according as the best kinds of Scotch or Lancashire coal were used, or the inferior sorts of Staffordshire. At the hospital at St. Louis, at Paris, the yearly average, from the same amount of coal, was twelve thousand three hundred cubic feet of gas, which is equal to four hundred and ninety-three cubic feet of gas to the hundredweight of coal. PRECHTL estimates the produce at seven hundred cubic feet; so that the statements as regards the weight of gas vary from twelve to seventeen per cent.

The decomposition of the coal begins with the incipient red heat of the enclosing vessels, and continues, if large quantities are employed, several hours, the quantity of gas gradually decreasing towards the end. PECKSTON found that, in an eight hours' distillation, when the fire was uniform, and the vessels constantly red hot, the relative quantities of gas given off were, in the first hour, twenty; in the second, fifteen; in the third, fourteen; in the fourth, nearly thirteen; in the fifth, twelve; in the sixth, ten; in the seventh, nine; and in the eighth, about eight per cent. of the whole quantity. The cubic foot at the end, therefore, costs two and a half times as much as at the commencement. The quality of the gas, at the different periods of the distillation, however, must also be taken into consideration. For this purpose, it will be proper to glance at the ingredients of the gaseous mixture in

general, which, after the separation of the aqueous fluid and the tar, consists of—

Hydrogen,.....	H
Bihydride of carbon,.....	C H ₂
Olefiant gas,.....	C ₂ H ₂ , or C ₄ H ₄
Volatile hydrocarbon,.....	C ₆ H ₆
Benzol,.....	C ₁₂ H ₆
Carbonic oxide,.....	C O
Cyanogen,.....	C ₂ N
Sulphide of hydrogen,.....	H S
Ammonia,.....	N H ₃
Carbonic acid,.....	C O ₂
Sulphurous acid,.....	S O ₂
Bisulphide of carbon,.....	C S ₂
Nitrogen,.....	N

The carbonic oxide and a part of the free hydrogen, doubtless, have the same origin, being formed from the moisture in the coal, or from the first portions of aqueous vapor generated, which, passing over the incandescent coke, are converted into these gases. The nitrogen of the coal is obtained entirely as cyanogen and ammonia, partly in combination, and the latter is also found with the sulpho-cyanogen and the other acids, forming volatile salts; *free* nitrogen, on the contrary, is the residue of atmospheric air contained in the retort. Sulphide of hydrogen and sul-

phurous acid arise from iron pyrites, eviscerated by the coal.

The first four of the ingredients named, with the illuminating vapors of tar oil, form the proper bulk of the gas; the others are small quantities of impurities which should have been separated with the tar. Experiment has proved that the relative proportions of the four principal ingredients vary with the duration of the distillation. When chlorine is added to light-gas and the vapors of tar oil, a fluid compound separates, and the original volume is consequently lessened. The diminution which the volume of the gas suffers when mixed with chlorine is, therefore, in direct proportion to its illuminating power and to the value of the gas—the amount of olefiant gas and tar oil vapors which it contains. This explains the following results of a series of elaborate experiments by Dr. HENRY, who followed analytically, step by step, the whole course of the evolution of gas. He found that, at incipient redness, scarcely anything but hydrogen, atmospheric air, and some tar passed off, with hardly any illuminating gas; but that, after attaining that temperature, illuminating gas alone appeared, and this was composed of a mixture of gases in the following relative proportions:—

Time of collection.	Specific gravity.	Out of a hundred parts of gas from Wigan canal coal.				
		Chlorine absorbed	Carbide of hydrogen absorbed	Carbonic oxide absorbed	Hydrogen absorbed	Nitrogen absorbed
In the first hour,.....	0·650	13	82·5	3·2	0	1·3
.....	0·620	12	72	1·9	8·8	5·3
.....	0·630	12	58	12·3	16	1·7
Five hours after the commencement,.....	0·500	7	56	11	21·3	4·7
Ten do. do.	0·345	0	20	10	60	10

Consequently, as a general result, carbide of hydrogen is formed in decided excess, and the most luminous portion of this, which is condensable by chlorine, comprises only about one-fifth of the whole. These numbers also prove distinctly, that after about the fifth hour the quantity only increases, but the quality does not improve; indeed, this deteriorates so rapidly, that at the expiration of ten hours, the gas which passes over is hardly luminous when ignited, but burns with a very faint flame. The specific gravity, as will be seen, keeps pace with the quality of the gas, diminishing as the latter improves, and can thus far be taken as a test for its value. As pure olefiant gas has about the specific gravity of common air, 0·98, the density of the illuminating gas must increase with the quantity of olefiant gas contained in it; yet an extraordinary amount of carbonic oxide, specific gravity 0·97, or of carbonic acid, specific gravity 1·52, may give rise to errors of some magnitude.

The great increase of hydrogen, which at the last period amounts to sixty per cent., is remarkable, and important to the manufacturer—an augmentation which is no longer due to the decomposition of aqueous vapors, but to that of the carbides of hydrogen. It was long ago observed that these are decomposed at a bright red heat, and deposit a portion of their carbon on the sides of the vessels. MARCHAND's recent experiments show very clearly the progress of this decomposition. When olefiant gas was conducted through a red-hot

tube, and the heat constantly elevated, the gas passing off, collected in successive portions, contained the following quantities of carbon to one hundred of hydrogen:—

Hydrogen.	Carbon.	Nature and temperature of the gas.
100	614	Olefiant gas.
100	580	Red heat.
100	533	—
100	472	—
100	367	—
100	325	Intense white heat.
100	307	Light carbide of hydrogen.
100	7	Continued white heat, nearly pure hydrogen.

The Editor will now give a short account of each gas, with its preparation and properties.

HYDROGEN.—First in the table of the constituents of coal-gas is this element, which in its pure state is a colorless transparent gas, possessing a very low specific gravity. It may be obtained by the action of weak sulphuric acid upon iron or zinc. Some nails, or pieces of iron wire, or granulated zinc, may be introduced into a tubulated flask, and covered with sulphuric acid, diluted with six or eight times its bulk of water; an effervescence ensues, heat is evolved, and the gas escapes, which may be collected in the hydro-pneumatic trough. The hydrogen, however, which is thus eliminated, is never perfectly pure. When procured from iron, its smell is peculiar and disagreeable, in consequence, according to BERZELIUS, of its

containing a portion of volatile oil, formed by its union with a minute quantity of carbon, which all common iron contains. When such gas is passed through alcohol, much of the odor is absorbed by it, and on diluting it with water, it becomes milky. Obtained by means of zinc, the gas is perhaps somewhat more pure, but appears to hold a trace of zinc and of carbon in solution, and perhaps, in some cases, traces of sulphur and of arsenic. For the purposes of delicate experiments, hydrogen must be passed through a solution of potassa, and then exsiccated by conducting it over fragments of fused chloride of calcium; it should also be collected over mercury, and procured from *purified zinc*, and *pure* sulphuric acid, so far diluted as to act but slowly upon the metal.

Hydrogen is an uncondensable aeriform fluid; it is not absorbable by water, unless that liquid has previously been deprived, by long boiling, of common air, in which case a hundred cubic inches dissolve about 1.5 of the gas. It has no taste, and when perfectly pure is inodorous. It has great power of refracting light. It may be respired for a short time, though it is instantly fatal to small animals. M. MAUNOIR, after having breathed a quantity of this gas, found that his voice had become remarkably shrill. The intensity of sound is greatly diminished in an atmosphere of hydrogen; LESLIE, indeed, ascertained it to be more feeble than its rarity, compared with air, would have led him to expect. He placed a piece of clockwork, by which a bell was struck every half minute under the receiver of the air-pump, and after exhausting the air, filled the receiver with hydrogen; but the sound was then even feebler than in the highly rarefied atmosphere.

Hydrogen gas, says BRANDE, is the lightest known form of matter, and its equivalent, combining, or atomic weight, is below that of all other substances; it is, therefore, conveniently assumed as *unity* in reference to the *atomic weights* of all other bodies. In consequence of its extreme lightness, it is difficult directly to determine its weight with accuracy by the common process; but the researches of BERZELIUS and DULONG, and of Dr. PROUT, lead one to infer that its specific gravity, compared with oxygen, is as one to sixteen; one hundred cubic inches, therefore, of pure hydrogen gas at mean temperature and pressure, weigh only 2.1483 grains, and compared with air, its specific gravity would be nearly as seven to one hundred, or, more correctly, as 0.0694 to unity.

The low specific gravity of this gas is well and interestingly illustrated, by substituting it for common air in soap bubbles, which then rapidly ascend in the atmosphere, and may be kindled by the flame of a taper. The same circumstance also leads to its employment for the inflation of balloons, which, however, have of late years been generally filled with coal-gas. Small balloons may be purchased made of gold-beater's skin, or the lining membrane of the crop of a turkey, which, when filled with pure hydrogen, rise to the ceiling, their specific gravity being inferior to that of the surrounding air. Some of these, when filled with hydrogen, do not weigh more than forty-two grains, while the same bulk of air would weigh fifty-two, so that their buoyant power is about ten grains.

Hydrogen is inflammable, and extinguishes flame. When pure, it burns quietly, with a pale yellowish flame at the surface in contact with air.—*Brande*.

BIHYDRIDE OF CARBON—light carbide of hydrogen—is produced collaterally with carbonic acid, in the putrefaction of vegetal substances under water—hence its name, *marsh-gas*. It burns with a pale bluish light, rather stronger than hydrogen.

This gas is best obtained for experimental purposes by the decomposition of *certain acetates*, under the following conditions, first pointed out by PERSOZ, and described by DUMAS: forty parts of crystallized acetate of soda, forty of caustic potassa, and sixty of powdered quicklime, are well mixed and heated in a glass retort; the use of the lime being to prevent the action of the alkali upon the glass; at a heat approaching dull redness, the gas is abundantly evolved, and may be collected over water. The action is determined by the affinity of the alkaline bases for carbonic acid, and the instability of the acetic acid at high temperatures, an equivalent of acetic acid and one of water producing carbonic acid, which combines with the soda and potassa, while, at the same time, light carbide of hydrogen is formed, and passes off, as shown by the following formula:—

A mixture of one equivalent of fused hydrate of baryta, and one of anhydrous acetate of soda, similarly treated, also yield a pure gas.

Sir H. DAVY found the specific gravity of this gas to be 0.555, and, compared with hydrogen, as eight to one. One hundred cubic inches weigh 17.4 grains. According to FARADAY, its refractive power is 2.097, air being 1.000. When pure, it is of course unrespirable, but it is not very noxious when mixed with air. It is sparingly soluble in water, fourteen cubic inches of which take up about one of the gas. It is hardly sensibly soluble in alcohol or ether, and in oil of turpentine the proportion dissolved is not probably one-fifteenth of the volume of the fluid employed. It is inflammable, burning with a yellow flame, and producing carbonic acid and water; it has, when quite pure, scarcely any odor. It is not decomposed by electric sparks, but, when passed through a white-hot tube, deposits a portion of its carbon.

A hundred volumes of this gas require two hundred of oxygen for perfect combustion, which produces *water* and a hundred volumes of *carbonic acid*. One hundred volumes of carbonic acid contain a hundred of oxygen, or half the quantity consumed; the remaining hundred volumes, therefore, must have united with two hundred of hydrogen to form water; hence, this gas is composed of—

	Atomic weight.	Per cent.
1 Eq. of Carbon,	6	75
2 Eqs. of Hydrogen,	2	25
1 Eq. of Bicarbide of hydrogen,...	8	100

DAVY made several experiments on the combusti-

bility and explosive nature of this gas. He observed that when one volume was mixed with one of air, they burned by the approach of a lighted taper, but did not explode; two of air and three of the latter to one of gas manifested similar results. When four of air and one of the gas were exposed to a lighted candle, the mixture being in the quantity of six to seven cubic inches in a narrow-necked bottle, a flame descended through the mixture, but no noise was produced; one volume of gas, burned with six of air in a similar bottle, made a slight whistling sound; one of gas with eight of air, rather a louder sound; one with ten, eleven, twelve, thirteen, and fourteen still inflamed, but the violence of the combustion decreased. A candle burned in a mixture of one of gas and fifteen of air, with a greatly enlarged flame, without producing explosion. The compound which appeared to be of the greatest explosive power, was that of seven or eight volumes of air to one of gas; but the report produced by fifty cubic inches of this mixture was less than that resulting from one-tenth of the quantity of a mixture of two parts of atmospheric air and one of hydrogen.

In reference to the *degree of heat* required to explode this gas mixed with its proper proportion of air, it was found that a common electrical spark would not explode five parts of air and one of the gas, though it exploded six parts of air and one of the gas; but very strong sparks from the discharge of a Leyden jar seemed to have the same power of exploding different mixtures of the gas as the flame of the taper. Well-burned charcoal, ignited to the strongest red heat, did not explode any mixture of air and of the fire-damp; and a fire made of well-burned charcoal, that is, charcoal that burned without flame, was blown up to whiteness, by an explosive mixture containing the fire-damp, without producing its inflammation. An iron rod at the highest degree of red heat, and at the common degree of white heat, did not inflame explosive mixtures of the gas; but when in brilliant combustion, it produced the effect. The flame of gaseous oxide of carbon, as well as that of olefiant gas, exploded the same mixtures.—*Brande*.

OLEFIANT GAS.—Next in order is the chief constituent of coal-gas—namely, olefiant gas, a name derived from its property of producing, when in contact with chlorine at the common temperature, a peculiar aromatic oil resembling chloroform.

This gas burns with a beautiful brilliant flame, constituting the true illuminating principle of coal-gas. It is generally obtained by decomposing alcohol by sulphuric acid; for which purpose, two parts by measure of the acid, and one of alcohol, are put into a retort, and heat applied; soon after the mixture boils, the gas is evolved. It may be collected over water, and should be well washed with lime water, or with a solution of potassa, to abstract sulphurous and carbonic acids; it also retains a little ethereal vapor, which may be removed by agitating it with weak alcohol, and afterwards with water. A more refined process for the production of olefiant gas is that of *MITSCHERLICH*, which consists in passing the vapor of alcohol into sulphuric acid, so far diluted as to have its boiling point reduced 325°—namely, about two parts vitriol,

specific gravity 1·8, and one of water. The acid is heated to the boiling point, or nearly so, and is then put into the receiver, A, Fig. 89. The flask, or tubulated retort, B, contains alcohol. On the application

Fig. 89.

of heat to the latter, its vapor passes, by means of the tube, C, into the hot acid, and is converted—catalytically—into olefiant gas and aqueous vapor, which, after passing through a Woulfe's apparatus, D D, escape by the tube, E, together with a little alcohol and ether, into the pneumatic trough, F. The gas continues its course upwards into its recipient, H, while the accompanying bodies just mentioned are condensed in the trough. By this process the acid is not discolored, and no sulphurous acid is formed.

The apparatus may be variously modified. Thus, when it is required that the whole of the alcoholic vapor should be transformed into the olefiant gas, the ebullition of the acid must be continued by means of a spirit or gas lamp placed under the receiver. When the acid is merely heated in the first place, decomposition proceeds only till the acid is cold. Still, for preparing a *small quantity* of gas, this condition is quite sufficient.

The specific gravity of olefiant gas, as usually prepared, is about 0·980, or, compared with hydrogen, as fourteen to one, and a hundred cubic inches weigh about thirty grains. According to *THOMSON*, its specific gravity is 0·9722—the same as that of nitrogen and carbonic oxide—and a hundred cubic inches at the temperature of 32° weigh 31·879 grains. Its refractive power is 1·818, air being one; and its specific heat, compared with that of air, is, according to *DULONG*, 1·53, and according to *DE LA ROCHE* and *BERARD*, 1·55, being greater than that of any other gas.

Under the combined influence of intense cold and pressure, *FARADAY* succeeded in condensing olefiant gas into a clear, colorless, transparent liquid, not solidifiable: its vapor exerts a pressure of 26·9 atmospheres at 0°.

Olefiant gas, when carefully purified, has little odor, though it is very difficult to get rid of traces of ether; it is inflammable, burning with a bright and highly luminous flame. It extinguishes a taper, and is quite irrespirable. Water absorbs about one-eighth its volume of olefiant gas, leaving an insoluble residue, which burns like light carbide of hydrogen.

MARCHAND states that one volume of olefiant gas requires, for perfect combustion, three of oxygen. When sulphur is heated in one volume of this gas, charcoal separates, and two volumes of sulphide of hydrogen result. As hydrogen suffers no change of volume by combining with sulphur, it follows that olefiant gas contains two volumes of hydrogen condensed into one; hence the quantity of oxygen required for its combustion. This compound is also decomposed by heat alone, as by passing and repassing it through a red-hot tube of earthenware or metal; it then gradually deposits its carbon, and is ultimately expanded into twice its original volume of pure hydrogen. An analogous transformation of the olefiant gas generated in the retorts of the gas-works is observed, and is connected with the deposition of several interesting forms of carbon.

When *one* volume of olefiant gas is detonated by the electric spark in a proper tube—which, on account of the violence of the explosion, should be very strong—with three volumes of oxygen, *two* of carbonic acid are formed, and water is deposited. Now two volumes of carbonic acid contain two of oxygen, so that the other volume of oxygen must have condensed two of hydrogen to form water. Hence *one* equivalent or volume of olefiant gas must contain *two* equivalents of carbon and *two* of hydrogen.—*Brande*.

VOLATILE HYDROCARBONS.—Next in order, among the constituents of coal-gas, are the volatile hydrocarbons, portions of which vaporize at a heat much below that of boiling water; consequently, parts of them are carried off by the coal-gas—the quantity found in the gas varying with the distance from the works in which it is generated.

BENZOL contains ninety-two per cent. of carbon, a far greater amount than even olefiant gas. When it is burned with an insufficient supply of oxygen, large deposits of carbon ensue. With a proper quantity of oxygen, this hydrocarbon affords a beautiful light, as may be observed when a stream of atmospheric air is transmitted through it during ignition. The peculiarly rich and illuminating power of the vapor of benzol, may be seen by passing it through the pale and almost invisible flame of hydrogen. This substance has been fully described in Vol. I., page 285, *et sequitur*.

CARBONIC OXIDE, which is rather an impurity than a proper constituent of coal-gas, may be very readily obtained, as *BRANDE* remarks, by *DUMAS'* process, which consists in gently heating oxalic acid with five or six times its weight of sulphuric acid; the mixture effervesces in consequence of the evolution of equal volumes of carbonic oxide and carbonic acid gas; the latter may be abstracted by a caustic alkaline solution, and pure carbonic oxide gas remains. In this case, the evolution of the two gases is caused by the abstraction of water from oxalic acid, which contains, in its anhydrous state, the elements of one equivalent of carbonic oxide, and one of carbonic acid; but these can only exist as oxalic acid when in union with water, or with a base, anhydrous oxalic acid not having been isolated. Crystallized oxalic acid is $C_2O_3, 3HO$, which, acted upon by three equivalents of sulphuric acid, $3(HO, SO_3)$, becomes $3(2HO, SO_3) + CO_2 + CO$;

the hydrated sulphuric acid remains in the retort, the carbonic acid is abstracted by passing the gases through a solution of caustic potassa, and the carbonic oxide passes off. Another source of carbonic oxide, suggested by *FOWNES*, is the action of ten parts of concentrated sulphuric acid on one part of pulverized crystals of ferrocyanide of potassium; the gas thus obtained is pure, and is evolved in the proportion of three hundred cubic inches from half an ounce of the salt.

Ferrocyanide of potassium contains cyanide of potassium, $K C_2 N$, and cyanide of iron, $Fe C_2 N$; they are converted by the sulphuric acid into sulphates of iron and potassa, sulphate of ammonia, and carbonic oxide; thus, in regard to the cyanide of potassium,

It not unfrequently happens that carbonic oxide is formed by the combustion of carbon when the supply of oxygen is inadequate to the production of carbonic acid; hence the lambent blue flame which sometimes plays upon a coke or charcoal fire, or is seen to issue from certain furnaces: this is, in fact, equivalent to passing carbonic acid over red-hot charcoal; so that $C O_2 + C$ becomes $2 CO$.

The specific gravity of this gas compared to hydrogen is as fourteen to one; and to atmospheric air as 0.9706 to 1.0000; a hundred cubic inches weighing 29.0979 grains. It is very fatal to animals, causing giddiness and fainting when respired mixed with atmospheric air. When breathed pure, it almost immediately produces profound coma. It extinguishes flame, and burns with a peculiar blue light when mixed with, or exposed to, atmospheric air. *DAVY* found that the temperature of an iron wire heated to dull redness was sufficient to inflame it. It has no taste and little odor; it does not affect vegetal colors, occasions no precipitate in lime water, and is very sparingly absorbed by water which has been deprived of air. When burned in dry air or oxygen under a bell-glass, no moisture whatever is deposited, showing that hydrogen is not contained in this gas. Carbonic acid is the only result of this combustion.—*Brande*.

No change is effected in carbonic oxide when it is passed and repassed through a red-hot porcelain tube; nor is it altered at high temperatures by phosphorus, sulphur, nor even, according to the experiments of *SAUSSURE*, by hydrogen, though it is stated upon other authorities, that at elevated temperatures hydrogen does decompose it.

CYANOGEN.—There is no class of organic bodies, remarks *SIR ROBERT KANE*, of which there is more extensive and exact knowledge, than those which have cyanogen as their basis. The powerful affinities which this radical exerts, the simplicity of its constitution, and above all, the circumstance that one is able to prepare it in an isolated state, and to generate its compounds directly from it, as from those of a truly simple body, renders its history the most advanced portion of organic chemistry, and that to which the

analogy of mineral bodies, and the theory of compound organic radicals, is most undeniably applicable.

Cyanogen does not exist in nature ready formed; the kernels of peaches, plums, bitter almonds, *et cetera*, and the leaves of the cherry-laurel, yield, by distillation, abundance of hydrocyanic acid, but it is only then produced by the decomposition of other substances containing nitrogen.

This body may, however, be formed abundantly, and in a simple manner, by bringing its elements together at a high temperature, in contact with substances with which it may unite. Thus, when any organic matter containing nitrogen is calcined with potassa, the nascent carbon and hydrogen unite, and cyanide of potassium is produced; even with pure charcoal this occurs, nitrogen being derived from the air; and FOWNES has shown, that when a mixture of pure charcoal and potassa is ignited in a tube, and a current of nitrogen passed through it, the latter is absorbed, and carbonic acid gas being given off, cyanide of potassium is produced—

This mode of forming cyanogen has been made the basis of manufacturing processes on the great scale, and at present much ferrocyanide of potassium so formed is sent into commerce. By the action of ammonia also on ignited charcoal, cyanogen is generated in abundance; it combines with hydrogen and the excess of ammonia, and produces ferrocyanide of ammonium. It is by virtue of these processes, that cyanogen is obtained for its various applications in the arts.

Cyanide of silver, or cyanide of mercury, is to be introduced into a small glass retort, and heated to just below redness; a gas is evolved which must be collected over the mercurial trough; the cyanide of silver separates simply into metal and cyanogen; but when cyanide of mercury is used, a brown powder appears, the quantity of which is less as the temperature of its decomposition has been lower. The gas which comes over is, however, cyanogen absolutely pure. If a large supply of this gas be required, but not of absolute purity, it may be prepared by mixing boiling solutions of two parts of chloride of mercury, and three parts of ferrocyanide of potassium, and evaporating down the liquor; the dry mass, which is a mixture of cyanide of mercury, chloride of potassium, and cyanide of iron, gives out on the application of heat a very large quantity of cyanogen, nearly pure.

The properties of this gas are very distinct. It is colorless, has a sharp smell, which irritates the eyes. It

collects at the other end, *b*, as a colorless liquid. It is combustible, burning with a beautiful rose-colored flame, and producing two volumes of carbonic acid and one of nitrogen. It is constituted, therefore, of equal volumes of carbon vapor and nitrogen, the two volumes being condensed to one; hence, $0.836 + 0.976 = 1.812$, is its specific gravity. It dissolves abundantly in alcohol and water, but these solutions soon undergo very complex decompositions; the liquor being found to contain carbonic acid, hydrocyanic acid, ammonia, urea, and oxalic acid, besides a brown insoluble matter. A similar decomposition is produced much more rapidly by contact with aqueous ammonia. The composition of this brown matter appears to be C_4N_2HO . It dissolves in alkalies, and gives precipitates with the metallic salts; it has been hence termed *azulmic acid*. When heated it gives off cyanogen, which has been termed *paracyanogen*. This may be also formed by heating cyanide of mercury very strongly. It dissolves in hot nitric acid, and the solution gives, with water, a yellow precipitate, which combines with bases.

Cyanogen unites directly with hydrogen and with the metals, but its oxygen combinations require to be indirectly formed; there are three compounds of cyanogen and oxygen, which are all acids, and are polymeric bodies. It combines also with sulphur, and its compounds with this element have a remarkable tendency to form double and triple combinations.

The formula of cyanogen is indifferently written C_2N or Cy . Its equivalent number is 26.—*Kane*.

SULPHIDE OF HYDROGEN is best prepared by acting upon the sulphide of iron with dilute sulphuric acid. A lively effervescence ensues from the escape of this gas, and the solution contains protosulphate of iron; a gentle heat may be applied to facilitate the decomposition. In this process water is decomposed, its oxygen uniting with the iron, and its hydrogen with the sulphur; the change may be represented by the following—

This gas may also be obtained by acting on sulphide of potassium by dilute sulphuric or hydrochloric acid, in which case the result is similar to that already given. Sulphide of antimony and hydrochloric acid produce, when heated, very pure sulphide of hydrogen, the reaction being—

As sulphide of hydrogen is absorbed by water, it cannot well be collected over this liquid, except it be saturated with chloride of sodium, or be heated to above 90° , in which case its solvent power is very much diminished. It cannot be kept long over the mercurial trough, for the lead and tin, always present in the mercury of commerce, gradually decompose it, combining with the sulphur, and leaving the hydrogen free; the volume of the gas remains the same during this chemical reaction.

This gas is colorless and transparent; it is charac-

Fig. 90.

specific gravity is 1.819. If a quantity of cyanide of silver be sealed up in a strong tube, bent as in Fig. 90, and then heated at one end, *a*, the cyanogen is evolved and condensed by a pressure of about four atmospheres, and

terized by the fetid odor of rotten eggs, which, in fact, owe their peculiar smell to the production of this gas during their putrefaction. Its specific gravity is 1.177.

Sulphide of hydrogen gas dissolves in water, forming a solution used extensively as a reagent for most of the metals, from the solutions of which it precipitates metallic sulphides of various colors, by which many metals are distinguished.

When aqueous sulphide of hydrogen is exposed to the air, oxygen is absorbed, which combines with the hydrogen of the sulphur compound, water being produced, while the sulphur is set free, and appears as a milky precipitate. The nascent sulphur, however, in part absorbs also oxygen, and sulphuric acid is formed; hence the presence of this acid, free, in volcanic springs, as in the Rio Vinaigre in New Spain. If a solution of sulphurous acid be mixed with sulphide of hydrogen, half of the whole quantity of sulphur is precipitated, and the remainder is converted into pentathionic acid—

Sulphide of hydrogen is highly inflammable; if burned in a limited quantity of air, the hydrogen is consumed, whilst most of the sulphur is deposited. By means of chlorine or nitric acid, it may be completely decomposed; hence, chlorine acts as a disinfectant and purifier of sewers or rooms impregnated with the odor of sulphide of hydrogen. The annexed represents the decomposition:—

This gas is very poisonous; air containing only one eight-hundredth part producing death. Many of the metals decompose sulphide of hydrogen, particularly when heated in this compound, combining with the sulphur, and setting free the hydrogen. This occurs slowly, even at common temperatures; hence metals, as gold and silver, which are not oxidized by the air, are gradually tarnished by sulphide of hydrogen, which, exhaled from decomposing animal matter, is always present in the atmosphere. This gas, evolved probably by the action of water on the native sulphides of iron, at high temperatures, is a frequent constituent of mineral springs, and forms the class of spas termed sulphurous, such as those of Harrowgate, Lucan, and Golden-bridge. They are easily recognised by the fetid odor, by blackening a silver spoon, or by giving a black or brown precipitate with a solution of a lead salt.—*Kane*.

AMMONIA.—A full description of this volatile alkali is given in Vol. I., page 177, *et sequitur*.

CARBONIC ACID exists in the atmosphere as a product of combustion, and of the respiration of animals. Combined with metallic oxides, it forms the numerous class of native earthy and metallic carbonates, of which the carbonate of lime is much the most important.

It is a result, also, of the slow decomposition of vegetable substances, and is evolved in great quantity from the ground in volcanic countries. In the fermentation of sugar, it is produced in abundance along with alcohol. For the purposes of the chemist, it is generally prepared by decomposing marble, or calc-spar, by means of any strong acid; from its cheapness, and the solubility of the residual salt, hydrochloric acid is generally employed. Some fragments of carbonate of lime being placed in a wide-necked bottle, A—Fig. 91—the acid diluted with its own volume of water, is

Fig. 91.

poured in by means of a funnel, as represented in the figure, and the gas which is evolved is conducted through the tube, B, filled with fragments of recently fused chloride of calcium to remove any moisture. It then passes into the gasometer, C, to be made use of as required. The decomposition is as follows:—

The gas, owing to its gravity, may be received in a wide-mouthed bottle, which in this case is ascertained to be full by applying a lighted taper to the mouth, when it is immediately extinguished.

The properties of this gas are exceedingly striking; it is entirely void of color, and invisible; it is irrespirable, producing, when an attempt is made to breathe it, violent spasms of the glottis. If it be inhaled with air, even in the proportion of one to ten, it gradually produces stupor and death, acting as a narcotic poison. Its specific gravity is 1.511; hence, when disengaged in large quantity, whether by natural operations, or in the process of manufacture, it accumulates in all cavities within its reach, and may cause fatal accidents to animals which enter inadvertently. Workmen engaged in cleaning out dry wells or vaults, or the large vats from which fermenting liquors have been run off, should carefully observe whether a candle can remain for some time burning brightly at the bottom. In volcanic countries, chasms are frequently occupied to the

level of their surface by this gas, exhaled from the ground; and an experiment often shown, to amuse the traveller, consists in walking into such a cavern with a dog, which, holding the head near the floor, is almost instantly asphyxiated by the inferior layer of carbonic acid, whilst men, whose heads are above the level, breathe pure air; the dog, on being thrown into a neighboring pond, recovers from the stupor. Carbonic acid does not support combustion, a burning taper held in a jar of it being instantly extinguished; and the high specific gravity of the gas may be easily illustrated by placing a lighted taper at the bottom of a vessel holding air, and taking in the hand another containing carbonic acid; on inclining the latter, the heavy gas can be poured into that which contains the lighted taper—just as water may be emptied from one vessel to another—and falling to the bottom, extinguishes it.

Water absorbs its own volume of carbonic acid gas, forming a solution possessing an agreeably acid taste, and which sparkles when agitated. It changes blue litmus into a wine-red, which, by exposure to the air or heat, disappears. By means of pressure, water can be made to retain a large quantity of this gas, which escapes with effervescence when the pressure is removed, and is thus the basis of a variety of agreeable effervescing beverages. Carbonic acid dissolved in water precipitates solutions of lime and baryta white, forming carbonates, which redissolve in an excess of this acid.

Under a pressure of thirty-six atmospheres, carbonic acid may be liquefied. It then forms a colorless, exceedingly mobile liquid, having a specific gravity 0.83 at 32°, which is remarkable for its excessive expansibility by heat—this being four times that of air, or nearly one per cent. for each degree of Fahrenheit. When the pressure is suddenly removed from the liquid acid, it regains the elastic form with such rapidity, that, in consequence of the amount of latent heat with which the vapor combines, and which is abstracted from the liquid portion, part of it is frozen to a solid. Solid carbonic acid can thus be obtained in large quantity by an apparatus contrived by THILORIER. It is a white body in filamentous masses, like asbestos; it evaporates but slowly; it is very soluble in alcohol and ether; the latter solution produces by its evaporation the most intense cold known, estimated at *minus* 166°.—*Kane.*

SULPHUROUS ACID exists at ordinary temperatures and pressures in the gaseous form, but is one of the most easily condensable gases. It is always produced when sulphur is burnt in the atmosphere, or in pure oxygen, sulphur being incapable of passing directly into a higher degree of oxidation. In the burning of sulphur, the volume of sulphurous acid gas produced equals exactly that of the oxygen consumed.

When desired pure, it is usually prepared by decomposing sulphuric acid, by means of a metal not very easily oxidized, as mercury or copper. The metal combines with one equivalent of the oxygen of the sulphuric acid, and the sulphur with the remaining two equivalents of oxygen pass off as sulphurous acid gas; the oxide obtained unites with the sulphuric

acid to form a salt. Thus, taking mercury for an instance:—

If the temperature be not elevated beyond 200° in this process, it is black or suboxide of mercury which is produced— $\text{Hg}_2 \text{O}$ —but above that degree the red oxide— Hg O —alone is formed.

Sulphurous acid gas is absorbed by water; and hence, in order to examine its properties in that state, it must be collected over mercury. It is colorless and transparent, having a peculiar irritating odor, and cannot be respired. It is neither combustible, nor a supporter of combustion. It possesses bleaching properties, owing to which it is used in the arts to whiten straw bonnets, corn, silk, sponges, and other substances; if a red rose be exposed to the flame of burning sulphur, it becomes completely white.

When this gas is exposed to a temperature at zero, it condenses into a liquid, which boils at 14°, and produces by its evaporation intense cold.

Water dissolves about thirty-seven times its volume of this gas; the solution possesses the properties of sulphurous acid in a very high degree, and bleaches vegetal colors with great power; when kept for some time it gradually absorbs oxygen, and the sulphurous becomes converted into sulphuric acid.

Sulphurous acid is one of the most feeble acids known, and is expelled from its combinations by almost all acids but carbonic, to which the Editor has shown that it bears a most striking resemblance, and this even extends to the salts of both.

BISULPHIDE OF CARBON.—This remarkable substance is obtained whenever sulphur comes in contact with red-hot charcoal. Procured in this way, it contains an excess of sulphur dissolved in it, and must be purified by redistillation at a very moderate heat; when about nine-tenths have distilled over, by allowing the residue to evaporate spontaneously in a capsule, very fine right rhombic crystals of sulphur deposit.

The bisulphide of carbon is a colorless liquid possessing a very disagreeable alliaceous odor. It does not mix with water, but dissolves in alcohol and ether. Sulphur and phosphorus are soluble in it in large quantity. Its specific gravity is 1.272. It boils at 108°, and forms a colorless vapor, the specific gravity of which is 2.621. From its volatility, it obtained the name of *alcohol of sulphur*. While evaporating, it produces great cold; mercury may be frozen by suspending under the bell-glass a thermometer, the bulb of which is surrounded by cotton moistened with this fluid, and rapidly exhausting the air. It is very inflammable, burning with a blue flame, and producing carbonic and sulphurous acids. If a few drops of it be allowed to fall into a strong bottle containing oxygen, it detonates when touched with a lighted taper, like a mixture of oxygen and hydrogen. When the bisulphide of carbon is heated in contact with a metal, carbon is separated, and a metallic sulphide produced, which proves it to consist of one equivalent of carbon united with two of sulphur.

It is a powerful sulphur-acid, combining with the

sulphides of the alkaline metals, and yielding sulphur-salts, which are crystallizable; with the sulphides of lead, silver, copper, *et cetera*, it forms insoluble compounds, which correspond closely in composition to the ordinary carbonates. This substance, in fact, exactly corresponds to carbonic acid— CO_2 —the sulphur being replaced by oxygen, and hence it is often called sulpho-carbonic acid.—*Kane*.

NITROGEN is one of the two gases that constitute the atmosphere; it serves only to modify the effect of oxygen, and render the air fit and suitable for respiration: it is called nitrogen, from being the basis of nitric acid. It is also called by some chemists *azote*, from its incapability of supporting existence; but the former name is generally used, as a great many other gases have not the power of sustaining life.

Nitrogen exists in great quantity in the atmosphere;

Fig. 92.

it is readily procured by abstracting the oxygen from a confined portion of the air, when nitrogen remains almost entirely pure. Thus, if a small piece of phosphorus laid in a cup, *a*, floating in water, be set on fire, and a bell-glass, *a*, be inverted over it, the phosphorus, in burning, unites with the oxygen of the air, and forms white fumes of phosphoric acid. At first, from the great expansion of the air, caused by the high temperature of the flame, some bubbles escape from under the edge of the glass, but soon, even before the phosphorus ceases to burn, the water begins to rise in the bell, and finally, the clouds of phosphoric acid

gradually dissolving in the water, the residual gas will be found to occupy four-fifths of the original volume of the air, and to be colorless. Any combustible body would answer the same purpose, although not so perfectly as the phosphorus.

Independent of this source of nitrogen in atmospheric air, it may be obtained indirectly from other substances. Thus, most animal matters contain nitrogen in large quantity, united to carbon, hydrogen, and oxygen. If, therefore, some pieces of muscle, or albumen, or gelatin, be boiled in a retort with nitric acid, the oxygen of the latter combines with the carbon and hydrogen of the animal substance, forming different compounds, according to the temperature and the proportions, whilst the nitrogen of both is disengaged.

Nitrogen is a permanent gas, colorless, and transparent; it is absorbed by water only in very small quantity. It is lighter than atmospheric air, its specific gravity being 0.976, air being 1.000. It is characterized by the complete absence of the positive properties which distinguish other gases. Thus it does not support combustion or respiration; it extinguishes a taper, and animals are suffocated in it; but these effects appear to be due only to the absence of oxygen.—*Kane*.

AQUEOUS VAPOR.—It will be necessary merely to allude to the aqueous product of the distillation of coal, which is water holding in solution—

Carbonate of ammonia.
Sulphate of ammonia.
Sulphide of ammonium.
Chloride of ammonium.
Ferrocyanide of ammonium.

Most of these are fully described in Vol. I., page 183, *et sequitur*, and therefore, being only secondary products, need not be further dwelt upon.

OILY MATTERS.—The oily portion consists of—

Liquid.	{ Benzol, Toluol, Cumol, }	Neutral, {	$\text{C}_{12} \text{H}_6$	} Constituents of naphtha.
			$\text{C}_{14} \text{H}_8$	
			$\text{C}_{18} \text{H}_{12}$	
Liquid.	{ Anilin, Picolin, Leucolin, Hydrate of Phenyl-acid— }		$\text{C}_{12} \text{H}_7 \text{N}$	} Constituents of heavy oil of tar.
			$\text{C}_{12} \text{H}_7 \text{N}$	
			$\text{C}_{18} \text{H}_8 \text{N}$	
			$\text{C}_{12} \text{H}_6 \text{O}_2$	
Solid.	{ Naphthalin, Paranaphthalin, Pyren, Chrysen, }		$\text{C}_{20} \text{H}_8$	} Constituents of heavy oil of tar.
			$\text{C}_{30} \text{H}_{12}$	
			$\text{C}_{30} \text{H}_{12}$	

The Editor having learnt that the little information with reference to these ingredients, which is given in the treatises on gas hitherto published, has been felt as a want, will now refer to them individually; because, although secondary in point of importance, they are highly interesting, as being so intimately connected with the manufacture of coal-gas, which will constitute the principal subject of this article:—

Toluol.—When tolu balsam is distilled, there passes over a large quantity of benzoic, mixed with a little cinnamic acid, and a yellow liquid, which is a mixture of *toluol* and benzoic ether. By redistilling this, so as only to collect the portions which pass over between 265° and 285° , a distillate is obtained, which, when deprived of benzoic acid by distillation with solid caustic potassa, possesses the properties which belong to toluol.

It is a colorless limpid liquid, having an odor like benzol, volatile without residue, and boils at 226° ; the density of its vapor is 3.246. When it is acted on by concentrated nitric acid, and water afterwards added, an oily fluid is obtained, which is nitrotoluid, $\text{C}_{14} \text{H}_7 \text{NO}_4$, or, according to the Editor, toluol in which one equivalent of hydrogen is replaced by peroxide of nitrogen. By the action of sulphide of ammonium upon nitrotoluid, a yellow oil, which gradually solidifies into a crystalline mass, is obtained. To this substance, which acts as an *organic base*, the Editor gave the name of toluidin.

It crystallizes from its hot alcoholic solution in large broad plates. It is soluble in pyroxylic spirit, sulphide of carbon, and the fat and volatile oils, with the same facility as in spirit of wine; it is very sparingly soluble

in water; it has a vinous aromatic smell and burning taste; it has no action upon turmeric, but it changes red dahlia paper to green. With nitric acid it produces a fine scarlet color, whereas anilin, so treated, assumes a blue tinge. The extraordinary crystalline tendency which distinguishes the salt of anilin, belongs also to toluidin; its alcoholic solution almost immediately solidifies when mixed with an acid. Its salts are inodorous, and, with the exception of the platinum and palladium compounds, colorless. It gave on analysis the following:—

		Theory.	Editor.
14 Eqs. of carbon,	84	78.50	78.53
9 Eqs. of hydrogen, . . .	9	8.41	8.61
1 Eq. of nitrogen,	14	13.09	12.86
1 Eq. of toluidin,	107	100.00	100.00

Cumol occurs with hydrocyamid in Roman cumin oil, which, when distilled in an oil-bath, parts with a volatile acid, the hydrocyamid, at 165°, and in the residue the cumin oil remains as a colorless liquid, retaining a strong odor of Roman cumin oil, and a sharp burning taste; boils at 220°. By the action of cyanide of potassium, cumin oil is converted into a product resembling benzoin; in the air, and by the influence of oxidation, it yields cuminic acid. If cumin oil be boiled a long time with nitric acid, there is obtained nitrocuminic acid.

Anilin.—This base, which has the same constitution as picolin, exists in coal-tar oil, as well as in DIPPEL's oil; that which, by fractional distillation of the mixed bases, passes over at 182° is anilin. If sulphide of hydrogen be transmitted into an alcoholic solution of nitrobenzid, saturated with ammonia, sulphur is separated, and shortly the whole stiffens at 0° to a mass consisting of yellow crystalline needles; if this be heated to 212°, the solution filtered away from sulphur, and the filtrate distilled until the contents of the retort separate into layers, then is the lower one *anilin*, which is purified by distillation. It is a colorless fluid, strongly refracts light, has a penetrating odor, taste sharply burning, specific gravity 1.020, boiling point 182°; easily soluble in cold water, alcohol, and ether; if the aqueous solution be warmed it clouds, a portion of anilin being separated; it does not possess an alkaline reaction, but coagulates albumen; in contact with hydrochloric acid it forms a white vapor. When anilin is exposed to air it absorbs oxygen, and becomes yellow, brown, and resinous. A few drops of fuming nitric acid added to anhydrous anilin produce a fine blue color, which on slightly heating the mixture becomes yellow, and violent action ensues, sometimes followed by explosion; otherwise, the liquor passes through various hues, and crystals of nitropicric acid are ultimately formed. When anilin is added to a solution of hypermanganate of potassa, binoxide of manganese, oxalic acid, and ammonia are formed.

If to a solution of chloroxide of calcium—bleaching powder—anilin be added, a deep violet color is obtained, which in the presence of acids becomes red. By these reactions, anilin is distinguished from the other bases which have the same constitution. With the acids, anilin forms crystallizable inodorous salts, which are soluble in water and in alcohol, and which in the moist

air soon become rosy-red. Anilin precipitates the salts of the protoxide and sesquioxide of iron, alumina, and oxide of zinc. Cyanide, ferrocyanide, and sulphocyanide of potassium, do not react upon salts of anilin; tannin causes a brown precipitate.

Picolin occurs in DIPPEL's oil, as also in coal-tar, and in each part thereof, which, on distillation, goes over first, together with anilin. It is more volatile than anilin, and can, therefore, be separated by fractional distillation; what passes over at 133° is pure picolin. It is a flowing liquid of a strong, penetrating, somewhat aromatic smell, and sharp, burning, bitter taste; still fluid at 17°, boils at 133°, specific gravity 0.955; mixes with water, alcohol, and ether in all proportions; it is not precipitated by a solution of bleaching powder, does not coagulate albumen, reacts alkaline. Nitrate of silver, chlorides of barium and strontium, and sulphate of magnesia, are not apparently affected by picolin; tannin causes a white caseous precipitate. It combines with the chlorides of mercury, platinum, tin, and antimony. If picolin be added to a solution of chloride of gold, fine lemon crystals are obtained. The salts possess the property of crystallizing.

Leucolin or *Quinolin*.—This base is found in the least volatile portion of the basic oil of coal-tar, and is also formed when quin, cinchonin, strychnin, and thialdin, are heated with potassa. It has a disagreeable odor, and boils at 460°; its specific gravity is 1.081. It neutralizes acids, forming difficultly crystallizable salts. Its refractive and dispersive power is as high as that of bisulphide of carbon.

Hydrate of Phenyl, or *Carbolic acid*.—LAURENT obtained from that portion of the oil of tar which boils between 300° and 400°, *carbolic acid*, a compound which it has been found convenient to represent as the hydrated oxide of a radical which has been termed *phenyl*. It is obtained by agitating the oil with about twice its volume of *aqua potassæ*, pouring off the watery portion, and saturating it by hydrochloric acid. The carbolic acid separates in the form of a heavy oil, which may be purified by continuous distillation over a small quantity of caustic potassa.

Hydrate of phenyl is a colorless oily liquid, neutral to litmus paper, of a high refractive power, specific gravity 1.062. It has a penetrating odor, a pungent burning taste, and acts powerfully on the skin; it occasionally assumes the form of acicular crystals, which fuse at 94° and boil at 368°. It is slightly soluble in water. It forms crystallizable salts with the alkalis, which, however, retain an alkaline reaction; in many of its properties it resembles creasote. It unites with sulphuric acid to form sulphocarbolic or sulphophenic acid; with chlorine, bromine, and nitric acid, it yields various compounds.

Naphthalin is readily procured by the distillation of coal-tar, but its quantity is considerably enlarged if chlorine be transmitted into the menstruum, or if the latter be treated with bleaching powder, water, and sulphuric acid. Naphthalin always passes over last in the distillation of tar, mixed, however, with paranaphthalin, from which it is separated by treatment with alcohol, in which menstruum the latter is insoluble;

both bodies are deposited if the distillate be cooled to 10°. Naphthalin is purified by recrystallization from the hot alcoholic solution; it crystallizes by slow evaporation in thin, white, rhombic leaflets, and by slow sublimation in white, extremely light flakes of peculiar odor, and burning aromatic taste; insoluble in water, readily soluble in alcohol, ether, acetic acid, and a solution of oxalic acid; melts at 79°, boils at 212°; specific gravity 1.045. Easily distils with vapor of water is inflamed with difficulty, and burns with a sooty flame.

Paranaphthalin or *Anthracin*, which is found in coal-tar, is obtained by the method given in connection with naphthalin. It is procured pure by repeated distillation. Its properties are similar to those of naphthalin, but it does not fuse below 300°; completely sublimable; insoluble in water, scarcely soluble in alcohol or ether, but easily in oil of turpentine. If anthracin is boiled for a few minutes with nitric acid, it is converted into a yellow mass accompanied by evolution of nitrous acid; the mass stiffens after cooling, and if it be then washed with water and treated with ether, a substance remains which has not been thoroughly investigated. This body melts at a high temperature, and by cooling congeals to a mass consisting of long needles.

Pyren is isomeric with anthracin, and is found in tar from wood, coal, and oil. If the last be distilled until one-fourth remains, and the residue again submitted to distillation in a small retort until there is only carbon left, a reddish substance is obtained, which consists of pyren, chrysen, and empyreumatic oils; if this mixture be treated with ether, the chrysen remains, and if the ethereal extract be slowly evaporated, the pyren is then precipitated. It crystallizes from the boiling alcoholic solution in clear rhombohedral prisms; melts at 170° to 180°, and stiffens crystalline; inodorous, tasteless; insoluble in water, little soluble in ether and alcohol; on the contrary, readily soluble in oil of turpentine. Boiled with nitric acid it gives a combination, which consists of $C_{30} \left\{ \begin{smallmatrix} H_{10} \\ 2 NO_4 \end{smallmatrix} \right.$ *id est*, pyren, in which two equivalents of hydrogen are replaced by two of peroxide of nitrogen.

Chrysen.—The production of this body is stated in connection with the preceding; it appears as an inodorous and tasteless powder; insoluble in water and alcohol, and scarcely soluble in ether and oil of turpentine; fuses at 230° to 235°; solidifies crystalline. If it be boiled with nitric acid, it is completely dissolved, and a compound results, the composition of which is doubtful, but the Editor is of opinion that it must have the formula $C_{42} \left\{ \begin{smallmatrix} H_{12} \\ 2 NO_4 \end{smallmatrix} \right.$.

Besides these, there are various undescribed oils. Of these products, which are all contained in tar, it will be perceived that there is only oxygen in one, and this possesses acid properties. The first three are neutral, and constitute rectified coal naphtha. Three are alkaline, and contain nitrogen. The other four are solid and neutral. It is remarkable how few of the products of distillation have any oxygen, and how much they differ in this respect from those of wood; and that, where the oxygen does enter into combination, it

produces compounds having no illuminating properties, namely, carbonic oxide, carbonic acid, and water; and that, in one instance, it unites with a compound of carbon and hydrogen, producing an acid oil that is found in very small quantity in the tar.

The nitrogen of the coal forms ammonia, cyanogen, and a few alkaline oils; the latter is discovered in minute quantity in the tar. The products are nearly all compounds of carbon and hydrogen; and respecting these it is further to be observed, that when the hydrogen exists in greater quantity than the carbon, as in carbide of hydrogen, which contains two equivalents of hydrogen to one of carbon, the compound is permanently gaseous; this gas has been subjected to a pressure of thirty-two atmospheres, and to cold 166° below zero, without liquefying. Olefant gas, in which carbon and hydrogen exist in equal proportions, but in which two volumes of hydrogen and two of carbon are condensed into one volume, is durably gaseous; $C_{18} H_{12}$ is liquid; whilst naphthalin, $C_{20} H_8$; paranaphthalin, $C_{30} H_{12}$; pyren, $C_{15} H_3$; chrysen, $C_{12} H_4$, are solid. It may be safely asserted, that where the carbon and hydrogen exist in an equal number of equivalents, the compound will be gaseous, unless a very large number enters into the combination.

CHOICE OF GAS COAL.—What, then, are the practical inferences to be drawn from these statements? In the first place, it will be manifest that the greater the quantity of hydrogen, and the less oxygen and sulphur a cannel or coal may contain, the better it will be for gas-making; for the latter two rob the coal of a portion of its hydrogen, which is thereby prevented from uniting with a portion of carbon for the production of an illuminating gas. The coal should be selected as free from iron pyrites and sulphate of lime as possible, and lumps or masses of these should be thrown out, as they often occur in such a form in the coal.

EFFECTS OF WATER.—The coal should be moderately dried before being used, which can only be secured by its being stacked under cover, otherwise the rain would keep it saturated with moisture. The water, in its decomposition in the retorts, furnishes oxygen to the carbon of the coal, impoverishing the gas, whilst the hydrogen of the water does not combine with the carbon of the coal, but is liberated.

When the vapor of water is passed over red-hot coke and coal, and analysed, the resulting gas is found to consist, in a hundred volumes, of fifty-six of hydrogen, twenty-nine of carbonic oxide, 15.8 of carbonic acid, and light carbide of hydrogen only two-hundredths of one per cent. *It contains no olefant gas whatever*; this experiment is quite conclusive against the use of water or steam. It is evident that there are no products of the decomposition of water by red-hot coal or coke that possess any illuminating power. It has often been proposed to *pass steam into the retorts during the distillation of coal, but such a proceeding could have no good effect, but the contrary*. When it is considered that fifty per cent. of the whole of the gases proceeding from the decomposition of water by red-hot carbonaceous matter is hydrogen, it must be evident that this product would not only diminish the light of the gas with which it was mixed, but would give out such an

amount of heat during the burning of it as would render the use of such gas almost insupportable. The coal, then, should be dry; but it has been shown that air, passed between seams of coal, has been deprived of a portion of its oxygen, which must have combined with the carbon and hydrogen of the coal, and by so much have impaired its quality; further, it has been stated that coal and cannel are continually giving off gas—fire-damp—and this teaches that coal should be dried quickly and then used.

DISTILLATION OF COAL.—A few remarks may now be made on the changes which take place during the manufacture of gas by the distillation of coal in red-hot retorts. The nitrogen in gas is *entirely derived from atmospheric air*, admitted into the retorts during the charges, and by leakage in the apparatus, and is not a product of the decomposition of coal at all; it need not, therefore, be further dwelt upon.

The quality and illuminating power of the gas will be affected, not only by the quality, composition, and condition, wet or dry, old or recently obtained, of the coal or cannel, but by the degree of heat employed in its preparation, and the mode in which the operation is conducted. The chief products of the distillation are compounds of carbon and hydrogen, and these alone yield light; but of these, some are solids, others liquids, and some gaseous. The first two are of no value for the purpose of illumination, because their physical condition as solids and liquids precludes their use. The gaseous are three: one containing very little carbon—carbide of hydrogen—and, therefore, emitting very little light; the other two very rich in carbon—olefiant gas and volatile carbides of hydrogen—and giving light, though in small quantity. Mixed with these are found, besides the usual impurities—sulphide of hydrogen, ammonia, carbonic acid, *et cetera*—two gases, hydrogen and carbonic oxide, constituting the chief bulk of the mixed coal gas, which have been mentioned, but which are never evolved in natural operations. They are not necessary products of the process, but result from the mode of distillation.

The volatile hydrocarbons in coal gas, the exact nature of which has not yet been determined, and the proportions of which in the mixture are valuable, probably consist of propylene, C_3H_6 , FARADAY'S gas, C_4H_6 , and benzol, $C_{12}H_6$, with perhaps a portion of MANSFIELD'S allyl. In LEIGH'S earlier experiments on coal gas, which had been made from a different cannel to what is now employed at the Manchester Gas-Works, he found, pretty uniformly, that each volume of the gas, condensable by sulphuric acid or chlorine, required four and a half volumes of oxygen for combustion; subsequently, he ascertained that, when richer cannels were used, the condensable gases required a still larger proportion of oxygen for combustion. The fact, that a greater amount of carbonic acid is produced on exploding the gas with oxygen, than would proceed from a body of the series C_nH_n , shows that some other hydrocarbon, the carbon of which exists in a greater ratio to the hydrogen than in this series, is to be found in coal gas.

When the number of equivalents of carbon in a compound exceeds those of the hydrogen, it is, within cer-

tain limits, liquid: beyond these limits, solid: thus benzol, $C_{12}H_6$, in which the carbon is double the hydrogen; toluol, $C_{14}H_8$; and cumol, $C_{18}H_{12}$, are liquid;—whilst naphthalin, $C_{20}H_8$; paranaphthalin, $C_{30}H_{12}$; pyren, $C_{15}H_8$; and chrysen, $C_{12}H_4$, are solid.

The carbides of hydrogen may be conveniently divided into three classes. In the first, the number of equivalents exceeds that of the hydrogen; they are very rich in carbon, as benzol; these are either liquid or solid, and would give great light could they be burnt, but yield much smoke. In the second, the equivalents of carbon and hydrogen are equal in the compoundly as olefiant gas, volatile carbide of hydrogen; these are gaseous, but condensable by great pressure and intense cold, and give much light. In the third, the equivalents of hydrogen exceed those of carbon; these are altogether uncondensable, and give little light. When coal and similar organic matters are distilled at a comparatively low temperature, the carbon has a disposition to pass off with little hydrogen; the liquid carbides of hydrogen are formed; there is much tar and little gas, but the latter is rich. As the temperature rises, the liquid carbide of hydrogen diminishes in quantity and gaseous carbide of hydrogen increases; there is more gas and less tar. The heat still rising, the gaseous products become richer in hydrogen, and poorer in carbon; light carbide of hydrogen is formed in abundance; and at length, the temperature becoming still more elevated, pure hydrogen is evolved, as is always observed in the last hour's distillation in gas-making.

It is a well-known law of organic chemistry, that the higher the temperature, and the more advanced the decomposition of the substance, the simpler are the products.

When olefiant gas is passed through red-hot tubes, or lime, or, in fact, over any highly heated surface, it deposits a portion of carbon in a solid form, and escapes as a mixture of carbide of hydrogen and hydrogen. The same thing LEIGH has proved of naphtha, which deposits carbon in like circumstances, and is resolved into simple products.

The affinity between carbon and hydrogen seems to diminish with the temperature.

Is it not probable, that in the distillation of masses of coal, compounds rich in carbon are first formed, the carbon being in excess of the hydrogen? as the product rises in temperature, it deposits a portion of its carbon, the equivalents of hydrogen become equal, and a rich gas is formed; but this, getting still hotter, deposits more carbon; the hydrogen is now in excess, the gas is poor and gives little light; the heat still increasing, the affinity between the hydrogen and carbon is entirely disrupted, the remaining carbon is deposited, and pure hydrogen given off. Certainly all this can be effected artificially; and that it is so to a large extent in gas-making, is evident from the thick lining of almost pure carbon which soon forms in the interior of gas retorts, and which must proceed from the decomposition of the gas by the red-hot surface—must be deposited from it, in fact. Still there are, probably, three products at least of the decomposition of a liquid carbo-hydrogen: solid carbon, a gaseous product containing much hydrogen, and a solid hydro-

carbon having much carbon, the elements being divided amongst each other. When naphtha vapor is passed over red-hot quartz, it deposits carbon, gives off olefiant gas and light carbide of hydrogen, and forms a crystalline compound, naphthalin. With these facts, is it not reasonable to conclude, that there is a temperature at which, in the process of decomposition, olefiant gas and volatile hydrocarbon should be formed, and which yet should be unable to decompose these into compounds poorer in carbon, the intensity of decomposition being proportionate to that of the heat? The Editor agrees with LEIGH in thinking there cannot be a doubt that there is such a temperature, but it must be far below that at present employed for the manufacture of gas. Let the present system of gas-making be examined, says LEIGH, and the true source of the hydrogen and carbonic oxide, so invariably found in gas, and constituting so large a portion of its bulk, will be seen. It may be premised, that when carbonic acid is passed over red-hot coke, it is resolved into carbonic oxide, by taking up an additional equivalent of carbon.

When compact masses of coal are thrown in heaps, of a hundredweight and a half, into retorts heated to a bright redness, as is now done, they are exposed to two very different conditions: the surface of the mass, the exterior, in contact with the intensely hot retort, is instantly decomposed and charred; hydrocarbons, as olefiant gas, *et cetera*, are eliminated, which also, at this temperature, are partly decomposed and converted into light carbide of hydrogen and pure hydrogen, with deposition of carbon, which, with some undecomposed olefiant gas and volatile hydrocarbons, pass off from the retort. The interior of the mass, on the other hand, is for some time exposed to a very moderate heat, and a simple distillation is accomplished; those compounds that are formed at a comparatively low temperature, the heavy hydrocarbons, which would ordinarily be in a liquid state, are eliminated; a portion, rising into vapor as it reaches the hotter surface, passes off with the gases formed, and condenses again when it has left the retort in the form of tar; but that portion of the vapor which, in its passage, comes into contact with the red-hot surface of the exterior of the mass and of the sides of the retort, deposits a portion of its carbon, and is resolved into simple compounds, olefiant gas and volatile hydrocarbons, which themselves partly undergo the change already described. As the heat penetrates to the centre, and a red-hot mass of charred material of considerable thickness comes to surround the decomposing coal within, as happens towards the end of the distillation, the whole of the hydrocarbons, namely, light oils, volatile hydrocarbons, olefiant gas, and even light carbide of hydrogen itself, that are eliminated, are decomposed in passing over such an extent of heated surface, and pure hydrogen is almost alone evolved. The carbonic oxide, which is formed from the union of the oxygen of the coal, and of the air admitted with the carbon of the coal, is also partially decomposed during the whole of the process, but in an opposite direction; not by depositing carbon, but by taking up more, and being converted into carbonic oxide, which is evolved with the gas.

These are the true sources of the hydrogen and carbonic oxide in gas; they are not necessary results of the distillation, but products of the decomposition of the distilled matter. It has been perfectly ascertained by LEIGH and other chemists, that when olefiant gas is passed through a nearly white-hot porcelain tube, it is entirely decomposed, depositing the whole of its carbon, and giving off pure hydrogen.

The greater the heat employed, then, in the process of gas-making, above a certain limit—namely, that requisite for the decomposition of the liquid hydrocarbons—the greater will be the bulk of the gas, and the poorer its quality; the more light carbide of hydrogen, hydrogen, and carbonic oxide it will contain, and the less volatile hydrocarbon and olefiant gas. The analysis of the gas will, therefore, furnish a test of the excellence of the process employed in the manufacture, and a check on the workman, by exhibiting, in the relative amount of hydrogen, and of the illuminating hydrocarbon, whether the heat has been too great. A large quantity of gas may be made from coal, and very badly made. *The mere amount of gas produced is no proof of the excellence of the manufacture.*

Cannel yielding eleven thousand feet of gas per ton, of specific gravity 1.600, would furnish, for every hundred pounds distilled, about—

	Pounds.
Gas,	22.25
Tar,	8.50
Ammonia water,	9.50
Coke,	59.75
	100.00

These proportions will vary considerably, but still the numbers will represent a general average of produce. It has been shown above, that considerably more than one-third of the weight of the gas produced is distilled from the cannel in the form of tar, which contains, and is almost entirely composed of, the richest carbo-hydrogen, and very little oxygen; whilst the gas, as it contains only about forty-five per cent. of compounds of carbon and hydrogen by measure, amounting to about half its weight, has really only eleven pounds, or something near that number, of carbo-hydrogen, and of this only about four pounds will be olefiant and richly illuminating gases. So that the tar truly holds as much illuminating matter, or nearly so, as exists in the gas—not twice as much, as would appear from the numbers; for it must be borne in mind, that in the oils composing the tar the carbon exists in much greater proportion than the hydrogen—one of the lightest, benzol, being a compound of carbon, twelve; hydrogen, six—naphthalin and the solid carbides being represented by carbon, twenty; hydrogen, eight; and even higher proportions of carbon. So that, in the decomposition into illuminating gases, much of the weight must be lost in the form of deposited carbon. It will be now tolerably apparent, that in the form of distilled matters nearly one-half of the illuminating portion derivable from coal and cannel is lost to the gas. It is probable that a perfect system of gas-making would produce, from good cannel, a compound containing twenty per cent. of olefiant or other illuminating gases.

MANUFACTURE.—The process followed at the Liverpool gas-works, where the purest gas in the kingdom is produced, will first be cursorily described, so as to give the reader an insight into the manufacture; and, subsequently, the several parts of the apparatus will be treated of fully and separately.

The mode of decomposing the coal is a point of great importance; because, upon its successful results the advantages of gas-lighting, as far as respects economy and profit, principally depend.

The vessels employed for distilling or carbonizing the coal are called retorts, and may be either of cast-iron or fire-clay. Fig. 93 shows a general plan of the gas-works above-mentioned, and Fig. 94 a sectional view, in which A A represents the fire, and B B the retorts.

To introduce the coal into the retort a shovel is used; but in stations having small ones, the coal is placed in a long semicircular iron shovel, or scoop, which, being inverted, spreads it in thin layers, so that every portion of it may be exposed to the action of heat. In order that the required substances may be evolved in sufficient quantities, there must be the requisite amount of caloric; for if a piece of coal is to be extended to two hundred and seventy times its bulk, the heat applied must be equal to the force requisite to produce a separation and expansion of its equivalents.

The heat should be sufficient at the outset to extract the maximum quantity of gas. During the first two or three hours, the greatest proportion of tar is produced. This is accounted for on the principle, that the temperature in the retort is not high enough to maintain the material in a gaseous form, and hence the large amount of tar. If the retort should be too hot, some of the heavy gas will be decomposed, depositing part of its carbon, and forming light carbide of hydrogen; if, on the contrary, it is not sufficiently hot, there will be formed, as just stated, a large proportion of tar, and the gas will be light and of a bad quality. The charge should not be left in too long, as the last portions consist chiefly of hydrogen and carbonic oxide, both of which have a most injurious effect upon the quality of the products. The process requires five, six, or eight hours, according to the nature of the coal and the shape of the retort.

Previous to drawing the charge, the lid is loosened and a light applied; this precaution is necessary to prevent explosion, or what the stoker denominates a *rap*. At large establishments, the retorts are not suffered to lose their heat, but as soon as the incandescent coke has been taken out of them, are immediately replenished with fresh coal, and the operation renewed.

Inasmuch as the coke is withdrawn in a state of redness, the heat required to raise it to that temperature is lost. To remedy this, CROLL introduced the practice of burning the coke as fuel, immediately after its removal, and this plan is said to cause a saving of ten per cent.

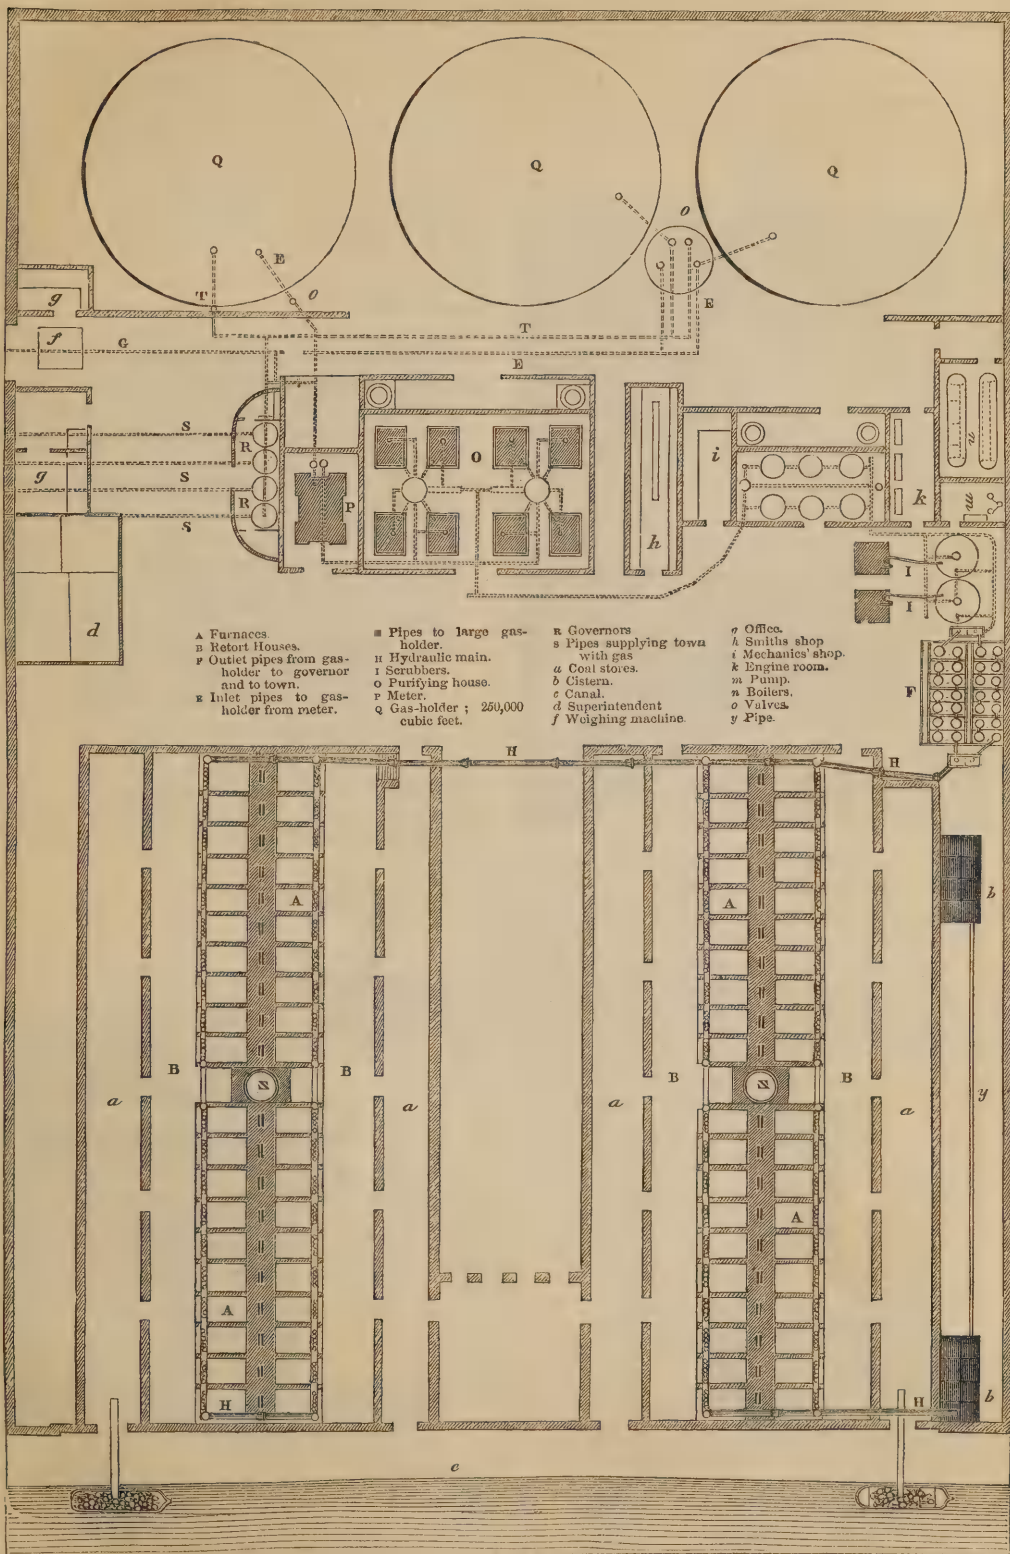

The dense vapors which pass from the retort are conveyed through the ascension pipes, c, Fig. 94, into the hydraulic main, H H, which runs the entire length of the house, and to which all the retorts are connected. Its position must be perfectly horizontal; it is used to cut off the communication between the retorts, when one

or more benches are charging or open. This is shown in Fig. 95. One end of it is perfectly closed by means of a flange, and the other has a similar one. On the top is attached a pipe, through which the gas passes to the condenser. In the outside of this end a piece of iron is placed, so that the water in the main is preserved at a certain height, and cannot sink below the proper level required for the operation. An enlarged view of this is shown at E, Fig. 96. The dip-pipes descend so far into the hydraulic main, D, as to be immersed in the water about three inches; by this means the gas is forced to pass through a quantity of liquid before it can enter the upper part of the main to escape, and becomes partly condensed, and deposits tar and ammonia, but, owing to its superheated state, portions of these products are still retained, and must be separated by further condensation. To effect this, the gas is conveyed into a double set of refrigerating pipes, F F—Fig. 94—closed at the top, and opening into a box, G, at the bottom, a section and plan of which are shown in Figs. 97 and 98. The latter receives two pipes, and constitutes one pair of the series which are united by a short connecting-pipe at the top, as seen in the drawing. The greater the quantity of cold surface the gas is exposed to, the more complete the condensation, and a state of stillness materially aids the deposition of the tar. Thence the gas passes through the scrubbers, I I—two large towers filled with paving-stones—and at the top of which one of the pipes, K K, for conducting water, which is kept continually percolating, is shown in the enlarged view of K—Fig. 99. The condensers and the scrubbers are relieved of their tar and ammonia by the cisterns, L L, which are conveniently placed under ground. The ammonia, being the lighter, floats at the top, and is therefore easily separated from the tar. In the articles AMMONIA and ASPHALT, the purposes to which both products are applied are enumerated. From the scrubbers the gas passes through the exhausters, M M M—a series of apparatus introduced into modern gas-works, for the purpose of drawing off the gas and relieving the pressure in the retorts. They are worked by a shaft, T, connected with the engine.

The gas then enters through a pipe, b b, into the chamber, N, a plan of which is given in Fig. 100. From this it is conducted, as shown by the arrows, through the dry lime purifiers, O O, where it parts with its carbonic acid and sulphide of hydrogen. It is next conveyed to the station-meter, P; thence to the gas-holder, Q; then into the governor, R, the principle of which is illustrated in Fig. 101; and, lastly, to the main, S, supplying the town with gas.

Whoever enters, says DODD, for the first time into a retort-house cannot fail to be struck with its appearance. The iron roof and floor—the absence of windows, machinery, and work-benches—the curious appearance of the walls, covered over with complicated iron-work—the darkness of the place—the appearance of the men,—all have an aspect of strangeness. But, at intervals of every hour or two, and especially at night, the visitor's attention is suddenly awakened to a startling scene going on within the building. A set of men are seen advancing to one part of the side apparatus; they turn the handles of what appear to be screws; several ex-

plosive reports are heard, followed by the removal of circular iron doors or covers, about a foot in diameter; a burst of flame then issues from each orifice from which a cover has been taken; and, on going in front of one of these openings, there will be perceived a mass of intensely burning coal, or rather coke, extending back to the depth of six or seven feet. Then will follow the

Fig. 102.

removal, by means of rakes, of all the burning materials from each aperture; then the hissing and steaming consequent on the wetting of the coke by buckets of water; and, lastly, the re-charging of the heated cavity with fresh coals. It is not until after witnessing this series of operations that a stranger can rightly understand the arrangements of such a place. Fig. 102 gives some idea of the retort-house.

Fig. 103.

Retorts.—As the form of the retorts in which the coal is distilled, and the material of which they are composed, are matters of paramount importance, it will

be desirable to enter fully into details with regard to them. They are usually of cast-iron, seven feet long, and one foot in diameter.

TOMLINSON states that, before being used, they are tested by being placed in water, and then forcing air through them; if any flaw exist, it is detected by the air escaping in bubbles. Each retort is generally in two pieces, which are connected by flanges and screws—namely, the *neck* or *mouth-piece*, and the *body* or *hinder part*, which, by constant exposure to the fire, soon wears out, and requires renewal, while the mouth-piece is but little affected. The retort is charged and discharged at the mouth, which is closed by a lid, and fixed by means of a screw and a holdfast, the joint being made tight by a luting of clay, or refuse lime from the purifier. The gases which are generated from the coal escape from the retort by a wide tube, cast into the mouth-piece, and shown in Fig. 103, rising up therefrom. The best form for the body of the retort for obtaining a large quantity of gas in the shortest time, was long a matter of discussion.—Tomlinson.

That shape of retort would be best which would bring the whole charge into connection with the red-

Fig. 106.

Fig. 105.

Fig. 104.

hot sides. Hence, at the suggestion of PRECHTL, the original circular form of retort—Fig. 104—was soon superseded by the elliptical one—Fig. 105—and this has been improved by bending in the lower surface—Fig. 106. With the same length of 6·5 feet, exposed to the

Fig. 107.

fire, one hundred and fifty pounds of coal, when they only half-fill the retort, will cover, in the round retort, a red-hot surface of ten inches in width; in the oval retort, a surface nearly of twelve inches. The layer

of coal, in the latter retort, is four inches thick, and about one-third nearer to the top of the retort than in the circular form. These advantages, which are self-evident, are strikingly shown in practice, the requisite time for heating being reduced to nearly one-half.—*Knapp.*

Fig. 107 shows the arrangement and position of the retorts, of which there are generally five placed pyramidally in one furnace. Fig 108 is a front view of the same. To the three fires of the furnace, A is the door, c the grate, and B the ash-pit, with a well, D—Fig. 107,

Fig. 108.

for occasionally drying lime-mud; E is one of the three arches which pass transversely over each fire and divide the flame, F is a large arch overspreading the retorts, G G, against which the flame breaks and escapes at the side. The conducting tubes, I I, rise side by side above the furnace, passing behind a large horizontal tube, H, called the hydraulic main, and lastly turning over above it, enter it, dipping down nearly to the bottom. As this main, H, is filled with tar, the mouths of the tubes, I I, are closed, and there is no connection established between the separate retorts. One may, therefore, be opened and charged, without in the least interfering with the process going on in the other. The greatest portion of the tar separates from the gas in H, which latter passes off through K, whilst the former is carried away by the tube, L, curved for the purpose of keeping H half-full, through M, to a tar cistern, which is shown at L, Fig. 94; H can be completely emptied by means of the tap, J.

A very hot flame, mixed with an excess of unconsumed air—oxidizing flame—is unnecessary for the evolution of gas, and deleterious, on account of the rapid destruction of the retorts which it occasions; everything, therefore, depends upon a uniform, steady fire. The destruction of the retorts is incredibly rapid, and dependent upon several circumstances; besides the combustion caused by the hot air of the fire, the sulphur in the coal converts the surface into sulphide of iron, which melts off, and, lastly, the deposit of carbon in the interior, is of no slight importance. This carbon is partly in the form of hair-like deposit, partly stalactitic, from the dropping of tar, but generally occurs as a coating, one or two inches thick, in concentric layers, and combined with iron to form graphite. The specific gravity of these layers increases rapidly from the inner-

most layer to those on the outside, from 1·7 to 2·3. The outermost contain 1·72 per cent. of iron, the inner layers less; sometimes they are so hard, that they will strike fire with steel, and can be polished like glass. Carbon, sulphur, and the oxygen of the air, are, therefore, conjointly destructive of the retort. The retorts suffer most from the air that enters at the door when the fire is poked, and attacks them whilst red-hot. To protect them from this, the stoking-hole is sometimes situated at the back of the furnace, in a continuation of the chimney, when the noxious draft passes away without attacking the retort.

Fire-clay retorts are now extensively used, especially in very large works; and, from all the Editor can learn, they are superior to cast-iron in every respect, as regards duration and the great quantity of gas they are able to produce. One great advantage which they possess over iron retorts, is the facility with which the carbon that accumulates on their interior can be scraped off. Retorts made of this material, which are charged and drawn at both ends, and are therefore termed *through* or double retorts, have been lately very largely introduced; their superiority over single or back-to-back retorts consists in the amount of space gained by leaving out the partition walls, and also the thickness of the ends of single ones. In addition to this, when iron retorts are employed, they become so choked up with carbon, that the charge of cannel has to be gradually reduced as the area of the interior of the retorts decreases. In *through*-clays this is obviated; and in order to remove the accumulated carbon, it is merely necessary to leave the retort mouths open, thus allowing a current of air to pass through, and the carbon will peel off in flakes if touched with a sharp bar; a portion may also be consumed. An iron retort will afford, according to various authorities, about seven hundred thousand feet of gas, whilst the same length of a through-retort of the same diameter has been known to produce six times that quantity. The amount of fuel required to heat the through-retorts efficiently, is as yet undecided: some engineers give it as their opinion that the amount requisite is the same as is necessary for iron retorts, whilst others affirm that they need a much larger quantity. Should the clay retorts become by any means cracked, a mixture, composed of the following ingredients, is found to be an excellent cement:—

	Per cent.
Fire-clay,	42·5
Loam-sand,	42·5
Glass,	10·0
Chloride of sodium,	5·0
	100·0

This compound is ground well together with water. The principle of sealing up the gas by a water lute, or hydraulic joint, is, however, the same in both cases, and affords another instance of those beautiful contrivances for using one fluid in the management and manipulation of another, which is much lighter and more elastic.

The Pipes for connecting the Retorts with the Main.—The pipes leading from the retort to the hydraulic main are not fitted in the retort itself, but into a sepa-

rate casting, termed the mouth-piece, which is commonly of the same size as the mouth of the retort, and is secured to it by a flange and bolts. The same kind of mouth-piece is used for clay retorts, which, instead of a flange, are provided with a ring, four inches in thickness and six in breadth, through which holes are cut to receive the bolts for securing the mouth-piece.

A bent pipe passes up from the mouth-piece to the hydraulic main, the straight part secured to it being called the stand-pipe, while the other straight part passing into the main is called the dip-pipe. The part connecting the dip and stand-pipe is named the bridge-pipe, and this part is usually provided with two bonnets, which can be removed when the pipe requires cleaning. The stand and dip-pipes vary in diameter from three to six inches, a very usual size being four inches. There are various modifications in the arrangement of pipes between the retorts and the hydraulic main. In England, the stand-pipe usually passes up to a height of four or five feet above the main, and is fitted at the top with a semicircular bridge, which connects it with the dip-pipe.

The Hydraulic Main.—This is a tube or trunk, H, Fig. 94, usually but not always of cast-iron, extending the entire length of the retort house, and varying from twelve to eighteen inches in diameter, and generally five-eighths to three-fourths of an inch in thickness, when made of cast-iron. Wrought-iron hydraulic mains are now beginning to be used, and will probably altogether supersede cast-iron, on account of their lightness and strength. These are usually made of larger diameter than the cast-iron, and put together in longer lengths. They are formed of three-eighths of an inch boiler plate. The ring forming the main is composed of two circular plates, and one flat piece on the top. These plates are made of two breadths, namely, about three and two feet, and about five feet six inches in length. They break joint with each other, by having their line of division alternately on opposite sides of the main, which is constructed in lengths of twenty-three feet, and at each end of this length, there is a flange three inches wide. At the end of each length, and also midway, is a division plate seven inches deep in the centre.

The cast-iron mains are generally of such a length as to reach over two benches, and the joints are made with bolts and nuts, and iron cement, in the usual manner. In old works, the hydraulic main is usually a circular tube; but of late years, D-shaped mains have been frequently employed, generally with the flat side downwards.

The hydraulic main, when first brought into action, is filled to about one-half with water, but the tar contained in the gas which passes into it is deposited, so that the sealing liquid changes its character, and becomes nearly all tar.

The hydraulic main being filled to the above height, the end of the dip-pipe passes through the water to a depth of three or four inches. The gas from the retorts is then conveyed through the dip-pipes, and bubbles up through the water, till it arrives in that part of the main above the surface of the liquid. The hydraulic

main, therefore, is the first receptacle in which the gas is collected, after its separation from the coal.

It perhaps will not be out of place to call attention, in passing, to the simple yet admirable contrivance exhibited in this apparatus, which is partly filled with a dense fluid for the purpose of forming a perfectly air-tight and gas-tight chamber, and cutting off all communication from this chamber to the retorts, while the passage of gas from the latter to the former is entirely free and open. Its *modus operandi* will be evident, if it be considered that the extreme lightness of the gas will always cause it to pass upwards through the tar, while, once arrived over its surface, it has no power whatever to displace the tar, and pass backwards. This exquisite contrivance is termed the water-joint, and the hydraulic main constitutes its first application in the gas manufacture. It is by this method that the chemist is enabled to store and confine his gases in the receivers of the pneumatic trough, and thus, by the use of denser fluids, such as water and mercury, to imprison the most volatile forms of gaseous matter in a mode which, for delicacy and subtlety, infinitely excels every scheme of mere mechanical fitting. It will be seen hereafter how largely this valuable principle of sealing up the aeriform fluids by denser ones, through which they can pass in one direction but not in the other, has been applied in the purifier, the gas-holder, and, in fact, in everything connected with the collection, storing, and distribution of the gas. At present, it may be sufficient to point attention to the value of this property, derived from the different densities of fluids, which gives both to the chemist and manufacturer a power over the aeriform bodies, which they could not hope to obtain by any other means.

Each of the pipes thus dipping into the tar of the hydraulic main freely delivers the gas produced in its own retort, and the liquid effectually prevents its return. However numerous may be the pipes entering into it, whether they contain gas or not, and whether the retorts are working or not, it is impossible that any gas delivered above the surface of the tar in the main can escape back.

The length of the dip-pipes should not be less than three feet, and is frequently made as much as five, in order to prevent the tar rising in the dip-pipes connected with the empty retorts as high as the bridge-piece. It is obvious that the pressure of gas from the working retorts will force the tar up a short distance into the empty dip-pipes, but this seldom equals three feet. As the hydraulic main is generally half filled with tar, its diameter must be so regulated that the latter forced up into the empty dip-pipes will not so far diminish the depth in the main as to uncover the ends of the former, because this would simultaneously unseal every one of them, and the gas would immediately escape.

The hydraulic main is sometimes placed in the solid structure of the brick-work over the retorts, but more frequently a little in advance of the ends, in which case it requires to be supported by columns. The hydraulic mains at the Great Central Gas-Works, London, are in the shape of a reversed D, eighteen inches in height and the same in width. There is one on each side of the stack

retorts. They are cast in lengths of nearly ten feet, so as to reach over one bench of retorts, and the joints are placed over the centre of the arches. Their thickness is five-eighths of an inch, with a two and three quarter flange at the ends of each length. The upright pillars to support the mains are hollow columns, seven inches at base, six inches at top, and five-eighths of an inch in thickness. A pillar is placed in the centre of each length, and the opposite pillars are tied together by bars of inch-round iron stretching entirely across the bench of the retorts.

Each length of the hydraulic main is usually provided with a partition, the top of which is level with the surface of the fluid, and the object of which is to keep it to the same height in every part of the main. Of course, where so much depends on the effective sealing-up of the ends of the dip-pipes, every care must be taken to fix the apparatus in a perfectly horizontal position, from end to end. When the hydraulic main is cast-iron, the holes to receive the ends of the dip-pipes are cast in it, and the flanges of the same are secured to the main by nuts and bolts, the joints being made with the usual cement, such as that employed for attaching the mouth-pieces to the retorts. When the main is of wrought-iron, the top is formed by a flat piece, to which the wrought-iron circular part of the main is attached by rivets, and in this flat piece the holes for the dip-pipes are cut by hand. One end of the hydraulic main is closed by a plate having the same section at the outside flange of the main, to which it is bolted and secured by iron cement. A similar plate is also bolted at the other end of the main, but this plate is provided with an orifice usually about half the diameter of the main itself. The lower part of this orifice is immediately above the level of the fluid in the hydraulic main, and the orifice itself corresponds with the exit-pipe, which conveys away the gas to the condenser. The flange of the exit-pipe is bolted on to the perforated end-plate of the main. It is usually provided, soon after leaving this apparatus, with a descending pipe to carry off the tar into the cistern below the condenser. The lower end of this descending pipe must be sealed either by its dipping several feet into the tar of the cistern, or into a small vessel which communicates with the latter. The descending pipe to carry off the tar is not absolutely necessary at this place, because the same office is sometimes performed by the siphon-pipe at the first bottom bend of the condenser.—*Hughes*.

Condenser and Scrubber.—A separate account of these is unnecessary, as the reader will fully understand their use and purpose from the description given of them at page 133, as well as by referring to them on the general section, F I K, page 135, and enlarged view, Fig. 99.

The Exhauster.—In describing this apparatus, which has been introduced into modern gas-works for the purpose of drawing off the gas and relieving the pressure in the retorts, Mr. HUGHES gives some interesting particulars, which are appended. The modern refinements insisted on with reference to the purity of the gas, all contribute to increase this pressure, as, every time the gas passes through a fluid of greater density

than itself, a resistance is occasioned, which adds to the pressure on the retorts, and this, at length, becomes so great, that means must be resorted to for diminishing it. In the first place, the contrivance of sealing the dip-pipes in the hydraulic main, requires the gas to force its way through several inches of tar before it can escape from the retort, and this is the first obstruction it meets with. In many works where dry lime is used in the purifiers, the gas is conveyed through water in the wash-vessel, where the gas is again resisted, and the pressure of course increased. In the dry lime purifiers and in the scrubbers, it is not considered that any sensible hindrance is opposed to the passage of the gas, but in some works both a washer and a series of wet lime purifiers are used, in which the force imposed becomes considerable, and an exhauster is found almost indispensable. The weight of the gas-holders also adds materially to the pressure in the retorts.

About twelve years ago it was ascertained by Mr. GRAFTON, in the course of some experiments at Cambridge, that the carbonaceous deposit in the retorts was due almost entirely to the pressure on the gas. Previously to this discovery, it was generally considered by the most scientific authorities that the carbon was due to high degrees of heat, and too great an extent of heating surface. In addition to the injury of this deposit to the retorts themselves, causing them to burn out with great rapidity, and the expense of frequently removing it, there is every reason to suspect that some of the very best constituents of the gas, namely, the volatile carbides of hydrogen, are decomposed and condensed in the deposit, and that the gas is thereby much impaired in quality. In addition to this, the pressure causes an increase in the quantity of tar, an effect which never takes place except at the expense of the gas. Mr. GRAFTON conducted his experiments in such a way as to show very practically the truth of the conclusion he had arrived at. By increasing the pressure till it became equal to a column of fourteen inches of water, he produced in a single week a layer of one inch thickness, and at the expiration of two months it had filled up nearly one-fourth of the retort. During this experiment an accumulation weighing ten hundredweight and twenty pounds was produced by the carbonisation of sixty-seven tons of Wall's End coal. Another trial, under entirely opposite conditions, was then made, all pressure being taken off except that arising from half-an-inch dip into the fluid of the hydraulic main. Under these circumstances, when the retort was again worked with the same description of coal for four months, scarcely any deposit had taken place.

The earliest form of exhauster used was a pump on the principle of the Archimedian screw, which was used for pumping the gas from a higher to a lower point, level with the surface of a small reservoir of water. The screw revolves in an opposite direction to that required for pumping up or raising liquids, and, at each revolution, the upper mouth of the helicoidal canal takes in a certain quantity of gas, after which follows the water. The gas descends along the spiral canal of the screw, in proportion to the rate of revolution in the latter, and having reached the lower extremity of the canal, passes

off by a pipe, with an excess of pressure, measured by the height of the surface of the water above the lower extremity of the screw.

Another kind of extractor, which does not require so rapid a movement as the Archimedian screw, consists of a circular drum with four divisions, formed by curved plates proceeding from the centre to the circumference. The wheel revolves in a cistern filled with water to the height of three-fourths the diameter of the wheel; and each of the chambers, formed by the divisions, carries down below the surface of the water a certain portion of gas, which is delivered out of the drum into a pipe passing off at the level of the centre of the wheel. This pipe opens into a chamber containing water about an inch higher than the upper surface of the pipe, and the difference of level between the water in the cistern and in the chamber which the gas now occupies indicates the difference of the pressure. If the force be not sufficiently reduced by passing the gas through one drum of this kind, it goes on to a second or a third, till the required diminution has been attained.—*Hughes*.

Probably the most improved form of exhaustor is that used at the Liverpool works, of which there are two sets, of three each, in operation. Exhaustors become indispensable where clay retorts are employed, these being porous in their nature. They necessarily take up some space, but repay the outlay, as the oscillation shown on the inlet pipe does not alter more than half-an-inch, whilst other exhaustors are known to vary many inches. Their construction is very simple. A pipe from the scrubbers runs under the three exhaustor cylinders, with branches to reach to the height of three feet; at the top of the branch pipe there is a valve, and a holder of sheet-iron fits loosely over this, which has also a valve upon it. The space between the inlet pipe and outer cylinder is filled with water, in which the gas-holder works. When the latter ascends, the gas is drawn through the inlet valve, while that affixed to the gas-holder is closed by pressure from above; on its return the upper valve opens and the lower one closes. Each holder discharges at every revolution of the shaft about eighteen feet, and thus the gas is pumped from the retorts. Each cylinder is connected

Fig. 109.

to the other by branches, placed near the top for the purpose of passing the gas through the purifiers, to which it is guided by the centre valve. They are

worked by a shaft, T, connected with a steam-engine, as shown in Fig. 94.

The Centre Valve of Purifiers.—At the majority of works as many as sixteen or even more valves are used for the purpose of guiding the gas into and out of the purifiers. But, by the adoption of one centre valve, as is done in the Liverpool works, the necessity for a number is obviated.

Fig. 109 represents a front view of this most important part of the role of the gas-making apparatus, in which one purifier, B, with which it is connected is shown in elevation, and another, B', in section. Fig. 110

Fig. 110.

is a plan of the same indicating the position of the four purifiers, B B' B'' B''', and the inlet and outlet pipes to and from each, by which the gas is made to traverse the

Fig. 111.

whole. In the general view—Fig. 94—this valve is seen in section, and Fig. 111 shows it more perfectly. In the elevation and plan, Figs. 109, 110, A is the valve, which is so constructed that the gas entering it by the inlet pipe, A', passes through an opening, as shown at a, Fig. 111, and thence flows through a conduit to

the first of three purifiers it has to traverse; the outlet which conducts it to division *b*, enclosed by the dotted line, causing it to pass into the inlet of the second purifier; the same arrangement answers for the outlet of second and inlet of third purifier. From that of the third, it enters through *d* to the division for one pipe, at the top of which there is an opening equal to the area of the pipe, through which the gas enters the upper part of the valve box. From this branches a duct which conveys the gas to the meter, as shown at *p*, Fig. 94. The blank division represented in the plan—Fig. 111—throws out of action the fourth purifier.

Circular pipes would answer all purposes as well as the rectilinear ones shown in the drawings, but a larger box would be required.

LIME PURIFIER.—Of all the substances which have been resorted to for the depuration of gas from sulphur compounds and carbonic acid, lime is the most universal, and the choice does not arise from its cheapness, but more on account of its superior effect in arresting those products which deteriorate illuminating gas.

It is employed in two states: in the one case the apparatus is termed the wet lime purifier, from the lime being made into a cream with water, and used in this condition; the other is known as the dry lime purifier, in which quick lime, barely slaked, is resorted to. Their comparative efficiency is matter of dispute among gas-makers.

Both these have an unequal repute for efficiency among gas-makers; but their merits will be best made known to the reader by giving a few brief descriptive sentences upon each.

Wet Lime Purifier.—Fig. 112 is an elevational section of a lime machine, and Fig. 113 a plan through *dd* in Fig. 112. *A* is the inlet pipe, through which the gas passes into the chamber, *B*, which is four feet dia-

—after having overcome the pressure of the column of water in the tank, *plus* the pressure in the gas-holders—will pass, and bubble up through the lime-water.

Fig. 113.

E is an arm made to revolve on the spindle, *s*; the parts *ee* of this arm continue through the aperture and over the ring, serving to keep the lime from settling, or obstructing the passage of the gas. *F* is the outlet for the purified gas. *G* is a stuffing-box, through which the spindle, *s*, passes. *H*, a mitre-wheel, connected to a water-wheel or steam-engine, for turning the spindle. *I* is a pipe, through which the lime-water is drawn off, when it has become saturated with the impurities of the gas. It will be observed, that by this contrivance the water can be completely drained off, by opening a slide-valve bolted to the flange of the pipe, *K*, without suffering the gas to escape along with it, because a column of water will remain in the tube, *I*, equal to the height of the bottom of the tank, measured from the inner radius of the curve of the tube, namely, twelve inches, which is always more than sufficient to overcome the pressure of the gas in the purifier, when the valve on the inlet-pipe, *A*, is closed, which should be done before that at *K* is opened. *L* is a cylindrical vessel, open at the top, for filling the purifier; it also serves to show the quantity of water required; when the machine is at work, the column contained in the vessel will be higher than that in the tank, by the pressure of gas in the gas-holders, usually about three inches.

At the end of 1813, an explosion of a serious nature took place at the Westminster station, owing to a volume of gas escaping from the purifier, which was placed in a building near the retort-house, coming in contact with the flues of the retorts. The windows of several houses in the neighborhood were shattered, and Mr. CLEGG was severely injured. The recurrence of such an event was afterwards guarded against, by drawing the refuse lime-water through a bent pipe, as shown above, always containing sufficient water to seal it.

The lime-water may be mixed in a cistern—having its bottom *above* the level of the water in the purifier when filled, and furnished with an agitator worked by hand—and drawn off by a hose into any of the ma-

Fig. 112.

meter, jointed to the lid of the purifier, and supported upon two cast-iron beams, *c*. On to the bottom flange of this chamber, a circular ring of thin wrought-iron plate is riveted, of such a diameter that its outside rim will be within five inches of the tank of the purifier. *D* is a hoop, supported from the tank by bolts, *d d*, *et cetera*, having its upper edge level with the before-named plate, and its lower edge four or five inches below it. The space left between this hoop and the ring is three-eighths of an inch, through which the gas

chines, care being taken to keep the mixture well agitated while passing. The proportions are one measure of paste-lime to three of water; that is, to every five bushels of paste-lime about one hundred and twenty gallons of water must be added. The size of the lime machines ought to be so regulated, that they will contain sufficient lime-water to purify the quantity of gas made in twenty-four hours, without having occasion to fill them higher than the water-line shown in the engraving.

Four lime machines are necessary, two being in action and two out, alternately. When that machine is spent through which the gas first passes, shut it off, and open a third, leaving the second to perform the duties of the first, and so on. The following extract from Mr. CLEGG's journal expresses his opinion on the construction and use of lime machines:—

The grand principle in the construction of a lime-water purifier, is to divide the gas as minutely as possible, at the same time avoiding unnecessary pressure. If the machine be well constructed, seven or eight inches pressure in the machine is quite sufficient. Two sets are necessary, in order to have a pair clean and ready for immediate use. The practice of working the contents of the vessel over again, by passing them from one to another, is mistaken economy.

The work performed by a lime-water purifier is generally computed by its contents in gallons, and the head of water or pressure opposed to the passage of the gas through it. Taking the latter at a constant quantity of eight inches, the computation is easy. Four thousand five hundred cubic inches of hydrate of lime—which, as has been before stated, is the quantity produced by reducing one bushel, or two thousand one hundred and fifty cubic inches of quicklime—mixed with forty-eight gallons of water, will purify ten thousand cubic feet of gas, if properly applied.

Notwithstanding, however, that the quantity of lime required may be well known, it is necessary to test the gas in its progress through the various purifiers. In some cases it is advisable to use the test every twelve hours, or oftener, in districts, for instance, where coal is of inferior and various qualities. Every morning, as soon as the superintendent arrives at the works, he ought to test the action of his purifiers, more especially if he has received a fresh supply of coal or lime. It is necessary only to drop a piece of paper into the plumbous solution, and hold it to the escape-hole of the purifier. The slightest coloration indicates impurity.

Dry lime purifier consists of a square iron box—two are shown at o o, Fig. 94—six feet long by five feet wide, and three deep. The inlet pipe is eight inches inside diameter, and enters at the bottom of the purifier. A few inches above its mouth is fixed a plate about two feet square, which serves the purpose of distributing the gas and preventing any of the lime falling into the inlet pipe. The purifier contains three trays or sieves placed six or eight inches apart, and resting on snuggs cast on the inside of the purifier: each tier contains four trays, each tray being about two feet eight inches by two feet four inches, so that one purifier contains in all twelve trays or sieves, the bottom of each being composed of round rods, five-tenths of an inch diameter, placed about half an inch apart. The top of

the purifier is an inverted box, six feet by five, and with sides and ends ten inches deep, fitting into a water lute twelve inches deep, so that the gas is enclosed by a seal of at least ten inches in depth of water; the outlet pipe passing out of the lid of the purifier is eight inches inside diameter, and is made in the form of a semicircle, the inside diameter of which is two feet; the other end of the semicircle joins another pipe that is fixed. Each end of the semicircle outlet pipe dips into an annular space containing ten or twelve inches depth of water, so as to form a water seal similar to that described for the cover of the purifier. These water joints greatly facilitate the removal of the semicircular pipe and the cover of the purifier whenever required for the purpose of cleaning out or otherwise, without breaking any solid joint or doing injury to any part of the machine. Mr. CLEGG states that two bushels of the hydrate of lime will spread over a surface of sieve equal to twenty-five square feet, with a depth of two and a half inches, which, in practice, is found about the best thickness; and that this quantity, which is equal to one bushel of quick-lime, will, in some places, purify ten thousand cubic feet of gas, while in other places double the quantity of lime will be required.

In most of the French gas-works the hydrate of lime is placed upon beds of moss, which are first spread on the trays, or the latter contain alternately a layer of moss and one of lime. The use of the moss is to subdivide the gas into the thinnest possible sheets and streams, so that every particle of it may be brought into contact with the lime.

The purifiers generally used in the French gas-works are from three to four and a half feet in depth, and they are generally made circular, from four to eight feet in diameter, according to the size of the works; in these are placed three or four trays, which contain layers of lime and moss. When the lime is spread upon moss, it is usual to employ rather less than a bushel of lime per square yard of purifier. In most of the French gas-works the quantity of lime used for purification is at the rate of two and a half bushels per ton of coal, which yield, on an average, less than seven thousand cubic feet of gas per ton. The usual calculations with them is, that a purifier with an area of one square metre, or ten and three-quarters feet, is required for every ten hectolitres—two thousand eight hundred pounds—of coal distilled. This proportion is nearly at the rate of one square yard of purifier for each ton of coal distilled. The calculation is made on the quantity of coal distilled in twenty-four hours, this being the interval at which the lime in the purifiers requires to be renewed. It is also made on the supposition that the purifiers contain three layers of lime, so that the proportion becomes three square yards of screen containing lime for every ton of coal distilled in twenty-four hours. The cover of the purifier is made of light boiler plate, provided with a border or rim, which dips into a ring surrounding the purifier, and filled with water, so as to make a perfectly hydraulic joint. The cover is also fitted with handles, by means of which it can be removed when the lime requires to be renewed.

The lime removes from the gas carbonic acid about two per cent., and sulphide of hydrogen about one per

cent. If the gas be properly purified, a paper dropped in a solution of acetate of lead, and held in the gas, will turn black if sulphide of hydrogen be present; if the gas be passed through lime-water, a milkiness will be produced with carbonic acid.

The dry lime purifier is generally preferred as being more handy, less noxious, and offering but little resistance to the gas, *et cetera*. Sesquioxide of iron has lately been introduced into the trays of the dry lime purifier. It ought to answer well, removing the sulphide of hydrogen completely in the following manner:

The resulting sulphide of iron would be of value to the manufacturer of sulphuric acid.

Station Meter, or Measurer, is used for the purpose of ascertaining the quantity of gas produced from the coal; likewise as a check upon the men's work; and also for comparing the gas sold through the consumer's meter with that delivered from the works. The principle upon which it is constructed is as follows:—The part of the meter by which the gas is measured is called the drum, shown at P, Fig. 94; it is a cylindrical vessel, supported at the front and back by an axis, and divided into four separate compartments. These are so contrived, that whilst the gas is entering on one side through the inlet-pipe, it is passing out at the same time from another compartment at the opposite end, and, in its attempt to escape through the water, imparts a rotatory motion to the drum proportioned to its capacity and the quantity of gas allowed to pass through in a given time. The primary cause of this motion is the impulse communicated to the gas from the retort, technically called pressure. The action of the meter depends on its being filled to a certain height with water, over the surface of which the gas is transmitted; the use of the water is to close the aperture through which the gas enters the drum, and it also gives the latter a steadier motion.

At the front of the meter a series of wheels are worked by a shaft communicating with the axis of the drum, which, by means of the index, are registered in cubic feet—from ten to ten millions feet of gas manufactured during any period. The station meter employed at Athol Street, Liverpool, is constructed to register seventy thousand cubic feet per hour—one revolution of the drum will pass about six hundred and fifty. It is the largest of the kind ever made. Fig. 114 is a front view of it. On the face is a *tell-tale*, which serves the purpose of pointing out every irregularity in the production of gas during the twenty-four hours.

The following accurate description is given by TOMLINSON:—In the centre of the *dial-field*—Fig. 114—is fixed a circular plate connected with a train of wheel-work, set in motion by an enclosed drum, through which the gas passes, indicating tens of thousands, hundreds of thousands, millions, and tens of millions of cubic feet of gas. Upon this round plate is fixed a disc of paper, divided into twenty-four parts, with subdivisions. Suppose the meter to register three hundred thousand cubic feet in twenty-four

hours, and the plate to be connected by wheels in the ratio of three to one to that index, which marks one

Fig. 114.

hundred thousand in one revolution; it is evident that the distance travelled by one of the twenty-four divisions of the plate from a certain fixed point, will indicate the quantity of gas made in one hour, or $\frac{300,000}{24}$

= twelve thousand five hundred cubic feet. Above this divided disc is a timepiece, to the minute-hand of which is attached a detent, furnished with a pencil, pressing by a spring upon the disc. As the minute-

Fig. 115.

hand of the timepiece revolves, the pencil, by means of a guide fixed to the meter-case, is regulated, so that in the first half-hour it will make a vertical line upon the paper, in length equal to the diameter of the circle formed by the minute-hand, measured from the centre to the point at which the detent is fixed; in the second half-hour the line will be retraced by the hand rising again. This arrangement supposes the divided disc to be stationary; but, as it is made to revolve on an axis, which is also the axis of the internal drum, set in motion by the gas, the pencil will make a series of curved lines, meeting the divided circle of the disc every hour, and the distance travelled from point to point will mark the number of cubic feet of gas made during every hour

of the twenty-four. If the production of gas is regular, the figures formed by the pencil will be so also; if, on the contrary, any neglect has occurred, the irregularity of the figure will detect it, and point out the hour and the amount of difference; because, if the speed of the revolving disc be decreased, the figure formed will approach nearer to the straight line; if increased, the points of intersection upon the divided circle will be further apart. The case of the station-meter is usually greatly ornamented, and bears an appropriate inscription.—*Tomlinson.*

Gas-Holder.—The next subject for consideration is the gas-holders, or vessels in which the gas is stored ready for delivery into the mains, which distribute it throughout the districts to be lighted. These vessels were originally termed gasometers, which name is even sometimes now applied to them; but as they have nothing whatever to do with the measurement of gas, but are merely vessels of capacity, the simple name of gas-holder appears more expressive and appropriate.

The earliest gas-holders were made in the form of cubes or parallelopipeds; but there were disadvantages in this shape, independently of the waste of material required to construct them of this form, as compared with that for a circular one of the same capacity. The corners and angles of the square figures were also found to need bracing, and other precautions were necessary, in order to render the resistance uniform. Wooden tanks were also at one time made for the lifting part of the gas-holder to work in, but this was at a time when they scarcely exceeded in size some of the large vats or backs in use at the great porter breweries. The construction of these wooden tanks was, in fact, entrusted to the back makers, who used to guarantee the duration of the vessel for some period of time agreed on. They were, in consequence, generally constructed in a substantial manner, but it is evident that the rapid increase which took place in the size of gas-holders required the adoption of a different material than wood. When a deputation from the Royal Society, with Sir JOSEPH BANKS at its head, visited the gas-works of the chartered company in Westminster, about the year 1814, they strongly recommended government to restrict the company from constructing gas-holders exceeding six thousand feet in capacity, to be confined in very strong buildings. When Mr. CLEGG published his work in 1841, he says *gas-holders are now constructed to contain two hundred and fifty thousand feet*. In 1853 all the new gas-holders of the Great Central Gas Consumers' Company contained four hundred and twelve thousand feet, and there is one in Philadelphia one hundred and forty feet in diameter, and seventy feet high, capable of containing more than a million cubic feet.

The modern gas-holder is a cylinder of plate-iron, made of sufficient capacity to contain the maximum quantity of gas produced in twenty-four hours; and in very large works, where several gas-holders are used, the joint capacity of all should be equal to this maximum production. In many gas-works the capacity of all the gas-holders somewhat exceeds the consumption of the longest night, but it is believed this excess in capacity is unnecessary. The cylinder which contains the gas has no bottom, or it may be described as a cylinder inverted

over a cistern of water, both the inlet and outlet pipes having their orifices above the surface of the water, so that the gas is hermetically sealed up within the holder, and can only escape through the outlet pipe. The mode in which gas is stored in the gas-holder bears a very exact analogy to that of collecting and storing pursued by the chemist in the laboratory, where the jar to be filled is inverted over a trough containing water, and the gas admitted into it by a bent pipe passing up through the water. In the chemist's method, however, the jar or gas-holder remains fixed, while the water is displaced by the gas; in the gas manufactory, on the other hand, the water is not displaced, but the gas-holder is raised by the gas flowing in.—*Hughes.*

The Editor deems a further explanation of this apparatus unnecessary. The reader will have a very good idea of the mode in which it is suspended by referring to Q, Fig. 94. Mr. ALFRED KING states that the pressure on the gas-holders varies from three to five inches—columns of water—but the distributing pressure, which is regulated by an instrument called a governor, about to be described, alters, according to the elevation of the district supplied, and the hour of the day or night, from four-tenths of an inch to two inches.

The Governor.—This is one of those ingenious self-acting machines which are equally admirable for their efficiency and simplicity. It is placed between the gas-holder and the principal main pipe, in order to regulate the pressure of gas admitted into the latter, and acts quite independently of any irregularity due to the unequal action of the gas-holder, or to other causes. The governor is important in another point of view, namely, where a town has several different stages of elevation, and where, without some contrivance, the pressure of gas passing through the mains would vary very much on each different stage. It has been found by experiment that the pressure in a main varies at the rate of one hundredth of an inch for every foot of rise or fall.

In the case of a district being below the works, a governor is seldom necessary, the works being generally, as a matter of convenience, placed at a tolerably low level; and it is found practically that a district lying even thirty feet below the works may be lighted without the intervention of a governor to increase the pressure, as the diminution due to the difference of level would be only three-tenths of an inch of pressure. But governors are especially necessary in towns, such as Bristol, Bath, Edinburgh, Liverpool, Lincoln, Nottingham, Exeter, and many others which have different stages of elevation; because the gas, as it reaches the higher part of the town, will act with so great a pressure as to produce very serious leakage in the pipes, besides the disadvantage of giving the upper districts an undue proportion of light at the expense of the lower. Separate governors for the regulation of pressure at different stages of elevation are not considered necessary, unless the ground has a rise of about thirty feet; and in order to carry out the principle of uniform pressure to the utmost advantage, there ought to be as many governors as the quotient of the whole elevation in feet divided by thirty. Every gas-work for lighting a town should have at least one governor, to regulate the pressure of gas passing from the gas-holders into the first main. Many towns

in flat situations, which have no elevations much exceeding thirty feet, will require only this one, but in other very hilly towns it would be advantageous to have several smaller governors to regulate the pressure for their different levels.

The governor is merely a miniature single-lift gas-holder—shown at R, Fig. 94—suspended from the centre, and furnished with an inlet and outlet pipe, the former having a conical piston suspended in it—Fig. 101—which regulates the admission of the gas in the reverse ratio of its pressure. The lifting part is usually a cylinder of very thin sheet-iron, about five times the diameter of the inlet pipe, so as to give plenty of room for the two pipes to stand inside, and leave a space above for the gas to occupy in passing through the governor. The tank is made of cast-iron plates, of a circular form, usually somewhat less in depth than the diameter, and with the capacity of about two cubic feet for every ten thousand feet of gas required to be passed through in twenty-four hours. Thus, a tank about five feet four inches diameter, and four feet six inches deep, will be sufficient for a governor to pass three hundred thousand cubic feet of gas in twenty-four hours. The lifting part or invert cylinder, R, is about the same depth, and about four inches less in diameter. The inlet pipe, which may be about twelve inches or less in diameter, is provided with a flange at the base, and is screwed to the bottom of the tank, where it passes up the centre through the water contained in the tank. The top of the inlet pipe is also provided with a flange, on which is screwed an annular casting, which contracts the opening to eight inches. In this inlet pipe is suspended a solid cone of iron, varying from six to fifteen inches in diameter at base, and about two at top. This cone is suspended from and attached to the centre of the roof of the lifting cylinder, R, so that the cylinder and cone rise and fall together. To the centre of the roof, on the outside, is attached a chain passing over a pulley, which sustains, at its other extremity, a weight so adjusted as nearly to balance the weight of the conical piston. It is evident that, when the pressure of gas is very small, the cone descends, and allows a large escape from the top of the inlet pipe; and, on the other hand, when the pressure increases, the cone will rise and contract the openings, so as to cause a diminished quantity of gas to enter. Of course the perfection of this action depends on an accurate adjustment of the weight, and when once this is effected, the regulation of pressure is so perfect as to leave nothing to be desired. The gas, when once admitted into the space above the inlet pipe, finds no impediment to its progress, and passes off by the outlet pipe without further hindrance. The cone is usually made of cast-iron, and is turned true in the lathe. The orifice at the top of the inlet pipe is also bored true, and of a conical form, so as to fit the base of the cone. The regulation of the weight and counterbalancing chain is very simple, and needs no further description.—*Hughes.*

The House-Meter.—This meter, by which the consumer registers his consumption, consists of one hollow drum or cylinder, revolving about a horizontal axis within another hollow drum or cylinder, the inner drum being divided into compartments for measuring the gas,

and revolving in water which occupies the lower part of the outer cylinder to a height above the axis, about which the inner drum revolves. The details of the construction may be varied, but the wet gas meters have this common feature, that the gas is measured in the compartments of a drum, which compartments are occupied successively by gas and water, the drum being made to revolve by the pressure or elastic force of the gas acting on the compartments of the drum in succession. The revolutions of the drum being registered by suitable apparatus, the quantity of gas which has passed through the meter, by so filling the compartments in succession, will be accurately measured.

In Fig. 116, the outer circle represents the outer case or drum of the meter, within which a drum divided into compartments, A, B, C, D, revolves about an horizontal axis, *e*. The gas to be measured is brought into the meter by a pipe passing horizontally in the direction of the axis of the inner and outer cylinder, and turned up at the end, so that its

orifice, *a*, may stand above the water level, *f, g*. The four compartments, A, B, C, D, are similar in every respect, each having an inlet, *b*, by which the gas enters the compartment, and an outlet, *c*, by which it passes out of the compartment into the upper part of the outer case, whence it may pass by a pipe, *k*, in any convenient

direction. The gas being admitted into the meter, will pass the inlet, *b*, into the part of the compartment, D, which is just rising out of the water; the gas presses equally on the surface of the water and on the side, *h*, of the compartment, D; the effect of this pressure on the side, *h*, is to cause the inner drum to revolve, whereby the compartment, D, is raised more and more out of the water, and, as it rises, it fills with gas, until it occupies, by the revolution of the drum, the position in space of the compartment C, as to which it will be observed that the inlet, *b*, has just dipped below the surface of the water, and the outlet, *c*, is just coming to the surface of the water. The outlet, *c*, having risen above the surface, the gas will escape into the upper portion of the outer case. As the gas passes out of a compartment in the situation of C, by the outlet, *c*, water will enter by the inlet, *b*, and as the drum revolves the compartment D having occupied the position in space of C and B, comes into the position A, when it is entirely emptied of gas and filled with water, until, by further revolution of the drum, the compartment having come again into the position of D begins to fill with gas, as already described. That which has been described for one compartment takes place for the other three, and it will be seen that there will always be two compartments discharging their gas into the outer case above the water level, one compartment

Fig. 116.

filling with gas, and as it fills causing the inner drum to revolve, and one compartment full of water. The motive power causing the inner drum to revolve, is the pressure of the gas in the mains as transmitted from the gas-holder at the gas works, and the quantity of gas will be ascertained from the number of compartments which have filled and emptied, that is, from the number of revolutions of the inner drum, which are registered by a train of wheel work and a dial plate in the usual manner. The gas so measured and passed through the meter is conveyed to the lights by a pipe communicating in any convenient manner with the outer case, and the action of the meter is suspended when the gas does not pass away. It will be observed that the quantity of gas measured will be affected by the height of the water in the meter, the portion of the compartment which is occupied by gas being greater or less, according to the level of the water, whereas the inner drum will revolve whatever the height of the water, within certain limits. If the water rises above the top of the supply pipe, *a*, the entrance of the gas may be stopped altogether, and if it sinks so low that the orifices *b* and *c* are not sealed or closed and opened simultaneously, the gas may pass through the meter without causing the inner drum to revolve. Hence every gas meter is or ought to be adjusted to a certain water level; if the water rise above this level each compartment will measure too little gas, and since the number of revolutions is the same whatever the available space in the compartment for holding gas, the consumer will be defrauded; on the other hand, if the water sink below this level, since the available space in each compartment is larger than was calculated on, the manufacturer will be defrauded. Various causes are in operation to occasion a variation in the water level, and the necessity of preserving it has given rise to several ingenious contrivances for discharging any excess or supplying any deficiency of water.

All this may be further illustrated by Figs. 117, 118,

Fig. 117.

and 119. In Fig. 117, the direction of the gas is marked by arrows. The box *a*, in which the inlet pipe valve is contained, is soldered tightly, having no communica-

tion with the rest of the case, except through the valve, the position of which is shown by the arrows: *b* is the inlet pipe projecting above the water line, conveying

Fig. 118.

the gas into the meter by the bent arm *c*—Figs. 118 and 119—rising above the water between the convex cover and the inlet hoods. *d* is a float attached to the inlet valve, fixed so that when the water falls below the centre opening the valve will close, and the gas cease to enter the meter. Motion is communicated to the train of wheel-work behind the index from a spiral worm, *u*,—Fig. 118—fixed on to the axis of the drum, working into a wheel, the spindle of which passes through the tube *t*, sealed by dipping under the water contained in the case.

Fig. 119.

There has been much discussion and dissatisfaction in Liverpool of late, with regard to the water meter, parties asserting that although the company had *lowered* the price of gas, still the bills, when they were sent in, were *higher* than they used to be. So many persons came forward and asserted this, that the Editor was applied to by Mr. WHITTY of the Liverpool Journal, to know in what way the above could be accomplished. The following question had to be solved: Is it possible by manufacturing inferior gas to compel the meter to register against the consumer?

In the Editor's opinion it is no matter what kind of gas, insoluble in water, is made, *the registration would be the same*; but if *atmospheric air* was passed into the mains and entered the meter in company with the *coal gas*, it would tell against the consumer, and the *light emitted* would be deteriorated. Mr. WHITTY remarks in reply to the Editor's statements, that experiments performed at the gas works justified them. It appears by introducing one-tenth of common air into the gas-holder charged with gas, that the meter registers ten per cent. or more against the consumer. Some denied that gas so mixed with air would burn, but the results showed that it does, and had no effect visible to the eye, which is an important fact.

The following table, extracted from a paper containing some experiments by Mr. BARLOW, on the comparative value of coals for the manufacture of gas, may be found useful, especially to persons who are compelled to use canal coal for enriching gas of low illuminating power:—

Name of Coal.	Number of experiments, the average of which is taken.	Produce of one ton of Coal.				Equivalent of one cubic foot of gas in grains sperm.	Consumption of gas per hour to give a light equal to one standard candle.	Value of the gas from one ton of coals in pounds of sperm.

Mr. BARLOW is of opinion that coals which contain more than thirty per cent. of volatile matter, require a higher temperature for their distillation.

As all the volatile matter afforded by coal is not combustible, it does not necessarily follow that the

coal which yields the largest amount of gas is the most valuable, although such is generally the case, as will be seen by the following tables, drawn up by Mr. SAMUEL HUGHES:—

Some practical gas engineers are of opinion that the quantities in the preceding table are larger than are usually obtained in the works. The following table,

by Mr. WRIGHT, in which the results of experiments on the distillation of cannel coals are placed in a very practical commercial form, will be found interesting:—

	Name of Coal.						
	Lesmahagow canal.		Ramsay's Newcastle canal.	Derbyshire deep main	Wemyss' canal.		Wigan canal.
	Exp. 1. Pounds per ton.	Exp. 2. Pounds per ton.	Pounds per ton.	Pounds per ton.	Exp. 1. Pounds per ton.	Exp. 2. Pounds per ton.	Pounds per ton.

	2240·	2240·	2240·	2240·	2240·	2240·	2240·
Cubic feet of gas,	11,681	9,878	9,016	9,400	10,976	10,192	9,408
Specific gravity,	0·540	0·650	0·604	0·424	0·670	0·691	0·478
Illuminating power, gas of specific gravity 0·361, being,	—	2·33	2·	0·8	2·47	—	1·5

The annexed tables, by Dr. FYFE, contain, in addition to the quantities of gas afforded by the coals, much valuable information upon the relative illuminating values of the gases, which he arrived at by the chlorine test. When chlorine is added to coal-gas, it forms with the olefiant gas and the vapors of tar oil—with those constituents, therefore, upon which the illuminat-

ing power depends—a fluid compound, which separates, and the original volume is consequently diminished. The diminution which the volume of the gas suffers when mixed with chlorine is, therefore, in direct proportion to its illuminating power, and to the value of the gas—to the amount of olefiant gas and tar oil vapors—which it contains:—

Coals.	Cubic feet of gas per ton.	Comparative value of coals per ton by quantity of gas.	Specific gravity of gas, air = 1000.	Condensation by chlorine per cent.	Duration by jet, five-inch flame.	Comparative value of gas by chlorine.	Comparative value of gas by durability.	Comparative value of gas by chlorine and durability.	Comparative value of coals per ton by quantity of gas condensed by chlorine and durability into account.

This table exhibits the quantity of gas afforded from a ton of each of the coals; the specific gravity of the gas; the amount of condensable matter by chlorine; the durability of the gas when burned by a single jet with a five-inch flame; the comparative value of the gas for affording light, as shown by the chlorine test, by the durability, and by these taken together, which,

when test is had recourse to, is the proper method to follow. It shows also the comparative value of the coals for the purpose of illumination by the combustion of their gases, as proved by the quantity of gas afforded by each, and also by the quantity and quality taken together:—

Coals.	Cubic feet of gas per ton.	Specific gravity of gas, air = 1000.	Condensation by chlorine, per cent.	Duration by jet five-inch flame.	Illuminating power, one foot sperm. candles = 1.0 grains per hour.	Value of one foot in grains sperm.	Comparative value of one foot in grains sperm.	Value of one ton of coals in pounds of sperm.	Comparative value of coals.	Pounds of coke per ton of coal.	Fixed carbon per cent. in coal.	Ashes per cent. in coal.	Pounds of sulphur per ton of coal.

Having given a full account of the manufacture of coal gas—the Liverpool works, as stated before, being taken as the standard—it will now be desirable to enter upon the fabrication of this compound from other sources, such as oil, resin, *et cetera*; and, in doing so, the Editor will draw largely from the admirable work of Drs. RICHARDSON and RONALDS upon *Fuel*, which has just been published. It contains concise and exact information upon the several heads that will now be discussed.

Resin Gas.—Resin could be distilled in the oil-gas apparatus, if it were fluid at common temperatures; but such not being the case, it requires to be liquified

by heat, or some solvent, before it is allowed to pass into the retort. Coal-tar naphtha is often used to dissolve the resin, or the oil which results from its own distillation. When the latter is employed, the flame from the furnace, before escaping into the chimney, is allowed to play upon the reservoir of resin. As the resin melts, it trickles through a sieve into a second division of the vessel, leaving the impurities and the solid portion behind, where it is mixed with an equal part of the resin-oil. Thus a solution which will no longer solidify is obtained, and with it the retort is supplied, as with oil in the former case. When the gas, either from resin or oil, has parted with its condensable

vapors in the coolers, it is in a fit state for consumption, no further purification being required.

According to RONALDS and RICHARDSON, one of the best arrangements of apparatus for making resin gas, and which has stood the test of practice, is that which has been extensively carried out by CHAUSSENOT, and is shown in Fig. 120. The resin is here melted without any additional solvent, and the oil or tar collected and disposed of as a secondary product. The draught to the fire-place, *P*, is regulated through the ash-pit by means of the plate, *G*, which can be moved horizontally backwards and forwards in the groove, *h*. The air traversing from below through the grate and fuel, *rr*, creates a powerful flame, which passing, in the first instance, through the apertures,

Fig. 120.

ggg, in the roof, plays round the retort, *A*, in the space, *M*, and then, before reaching the chimney, heats the vessel, *I*, containing the resin, by means of the flue, *NN*. If this vessel requires filling, the fire is shut off from *N* by the damper, *b*, and is allowed free egress at the aperture, *o*, by drawing back the damper, *c*. Both the dampers are worked by iron rings and rods from without. In this apparatus it is not necessary to dissolve the resin in tar-oil, because the vessel, *I*, in which the resin is melted, and the conducting tube, *H*, being con-

stantly surrounded by hot air, no solidification of the melting resin at the bottom, *f*, can take place. Combustible gases are generated by merely melting the resin, which may possibly endanger the whole apparatus. To avoid such contingencies, the edge of the resin cistern, *I*, is furnished with a groove filled with water, *uu*, into which the lid, *K*, dips at *vv*, and is consequently secured by a water-valve. By means of an aperture in the lid, the vapors can be conducted into the chimney or under the grate. The melted resin flows consecutively through *H*, *F*, and *x*, into the retort, *A*. Between *F* and *H* is a plate, *o*, with a funnel-shaped aperture in the middle, in which the conical end of the rod, *d*, is movable. If this is raised through the stuffing-box, *e*, a more abundant supply of melted resin is furnished to the retort; if it is pushed down, the stream diminishes, or the flow ceases entirely. The resin flowing from *x* is carried to that part of the retort containing the coke, by means of the inclined plate, *q*. The coke is prevented falling back in the retort by the grating, *l*, the gas escapes through a descending pipe, *w*, to the tar-cistern, *C*, and from thence through *E* to the coolers, *D*, which are immersed in water in a long trough, *R*. *C* is nearly always filled with tar, that the mouth of *w* may remain immersed; this, therefore, dips into *C*, whilst the gas-pipe, *E*, behind the sectional level in the drawing, only just passes through the material of the main, *C*. Apertures are constructed in several places, at *a*, *a'*, *a''*, and *a'''*, by which the apparatus may be cleaned at intervals; these are firmly closed during the process of distillation, by flat plates of iron firmly screwed on, by means of iron brackets, similar to that used for closing the mouth of the retort *a*. Distillation goes on continually in this apparatus, until the deposition of carbon renders a renewal of the coke necessary.

Resin contains ten equivalents of carbon, seven of hydrogen, and one equivalent of oxygen. Its atomic weight is, therefore, seventy-five. Supposing the whole of the hydrogen to unite with the quantity of carbon required to form olefiant gas of specific gravity nine hundred and seventy six, the utmost that could be produced from an atom of resin would be forty-nine parts out of seventy-five, or about two-thirds of its weight, accompanied by some carbonic oxide and carbonic acid. If any of the hydrogen is evolved uncombined, or in the form of light carbide of hydrogen, a proportionate quantity of carbon must escape conversion into gas, and hence the loss which must always attend the distillation of resin, even supposing that none of it were distilled unchanged, or converted into resin-oil.

Dr. FYFE obtained the following quantities of gas by distilling resin at different temperatures, of which he also ascertained the relative specific gravities and illuminating power:—

Temperature of distillation.	Quantity of gas per pound of resin.	Specific gravity of gas.	Per centage of carbonic acid.	Durability or quantity consumed per hour in jet 1.39 inch diameter, and five inch flame.	In Argand burner consuming five feet per hour, illuminating power was equal to candles.	Resin not converted into gas; fraction of quantity distilled.
	Cubic feet.			Cubic feet.	Per cubic foot.	
Heat employed for coal-gas, ..	10 [•]	640	10	1.2	2.45	One-half.
Dull red-heat,	6.2	657	6	1.25	2.27	Two-thirds.
Somewhat above dull red-heat, ..	8.42	419	8	1.43	—	One-half.
9 [•]	—	613	—	—	—	One-half.
In White's retort without water-gas,	8.8	57	—	1.12	2 [•]	Three-fifths.

He considers, therefore, that the quantity of gas that can be produced from resin in practice will not exceed eight or nine cubic feet per pound, that is, about one thousand cubic feet per hundredweight; that the gas, after being purified, will be of specific gravity not much beyond six hundred; the condensation by chlorine not much beyond eight or nine per cent.; a cubic foot of gas not giving more than the light of from two and a half to three candles.

Hydrocarbon, or Water-gas.—It is well known that water passed in the form of steam over red-hot iron, is decomposed; its hydrogen being liberated in the form of gas mixed with a little carbide of hydrogen from the carbon of the iron, while the metal becomes converted into oxide. If coke or charcoal be substituted for iron in this operation, hydrogen, carbonic oxide, and carbonic acid gases are produced in variable quantities, according to the temperature employed; carbide of hydrogen, according to Dr. FYFE, being only present in very small quantity.

Gas from Animal Matter.—In the distillation of animal matters, bones, flesh, *et cetera*, which has long been practised for the production of bone-charcoal and bone-black, a tar containing DIPPEL's animal oil, and gases, are generated. The illuminating power of the latter has recently attracted the attention of manufacturers. SEGUIN in particular has carried on the process on a large scale, making use of the gases. When the flesh of dead animals, which contains sixty per cent. of water, is employed, the latter must be removed by exsiccation before the material is placed in the retorts, which are kept at a cherry-red heat. The sulphur—a constituent of albumen, fibrin, *et cetera*—is chiefly found in the gas combined with carbon, and the nitrogen of the flesh as carbonate of ammonia. After being properly cooled, the gas is first passed through a solution of chloride of calcium, where carbonate of lime and chloride of ammonium are formed, and thence through pipes containing lumps of sulphur, which condense the bisulphide of carbon to the liquid state. The latter would be converted in the flame into sulphurous acid and carbonic oxide.

Gas from Wood and Turf.—Wood and turf are not well adapted for yielding gas for the purposes of illumination, but where coal cannot be had, or only at a very high price, they may be advantageously resorted to as a means for illumination, as may be testified by many communities at a distance from bituminous coal, which are in the enjoyment of gas-light obtained from one or other of these sources. The illuminating power of the gas liberated from these by distillation, is, it is true, inferior to coal gas; but it may be rendered even superior to the latter, by transmitting it through vessels containing naphtha or oil of turpentine, or retorts which are charged with charcoal kept incandescent by the application of external heat. These facts are entirely of recent discovery. Dr. PETTENKOFER of Munich claims the honor of being the first to prepare gas suitable for illuminating towns and dwellings, *et cetera*, from wood; and his invention is gaining more attention daily in Germany, where the consumption of wood-gas is already very large. The manufacture of gas from wood is stated to offer many facilities

and advantages which are not experienced in the distillation of coal; among these is that of expedition, the gas being freely evolved from the wood, and allowing the charging of the retorts to take place every hour and a half. The tar from the wood distillations is more abundant, and the charcoal is much more valuable than the coke. Further, in coal gas-works the retorts are rapidly worn out, owing to several causes, such as the superior temperature caused by the sulphur in the coal; but it is not so in the manufacture in question, for the heat of distillation is considerably lower, and sulphur is absent. In Munich, where wood gas is used, the usual U-shaped retorts are employed; they are charged with ninety pounds of wood, from which as much gas is obtained as will suffice for two hundred and eighty burners. Immediately on introducing the dried wood into the red-hot retort, gas is evolved, which passes off through an arrangement of pipes, mains, scrubbers, and dry lime purifiers in the usual way. The charcoal, when drawn out, is cooled with wet sand. LIEBIG and STEINHEIL give the illuminating power of this gas as *six*, coal-gas being estimated at *five*.

Oil-Gas.—It appears, at first sight, both inexpedient and superfluous to distil oil for the production of gas, when it is considered that oil can be burnt in lamps without any further preparation, while it loses carbon by deposition in the retorts. Purified lamp oil is consequently never used; but gas can be prepared from impure oils, train-oil, or refuse fat, with as much ease as from the purer kind. The manufacture of oil-gas is, therefore, under certain circumstances, an admirable means of using up such materials for the production of light as could not otherwise be employed, or could only be applied to the lowest uses.

In 1815, Mr. J. TAYLOR obtained a patent in this country for the manufacture of gas from refuse fatty matters, and his plans were carried out at the gas-works at Paris, Liverpool, Bristol, and Hull; but the cost of raw material not being able to compete with that of coal, the oil-gas manufacture has been discontinued in this country.

The experiments of HENRY, which extend also to this part of the subject, show at once the plan that must be adopted upon a large scale. The following account of the results obtained, and the process of the manufacture, is given in KNAPP's *Technology*:—

It appears that the oil-gas is superior to that obtained from coal, as is also shown by its density, and that the produce, dependent chiefly upon the temperature, is of the best quality when obtained at a low red heat. This temperature suffices to convert the oil into gas, but is not sufficiently high to decarbonize the gas to any great extent. The apparatus for obtaining gas by the distillation of oil is represented in Fig. 121. The retort, A, is filled with bricks, or lumps of coke, which very materially increase the red-hot surface, and promote the evolution of gas, shortening the time which the gas already produced has to remain in the red-hot vessel. The second cylinder, B, serves both as reservoir and hydraulic main, A and B being connected in two places, D and E. Oil flows from a large cistern above the apparatus in a constant stream through the

tube C into B, which is thus kept filled up to a certain level. From B, the oil descends through E to A, where it is converted into gas and tar, both of which are volatilized, and return through D to B. The pipe, D, is

Fig. 121.

bent, and its open end delivers just below the fluid level in B, so that the vapors of the decomposed oil must constantly pass through the reservoir of oil, and deposit their tar. The retort, A, is therefore constantly supplied, not only with oil, but with a mixture of oil and tar, in such a manner that all the condensed products return to the retort together with a fresh quantity of oil, until they are completely converted into gas. If the operation be conducted in a long tube, inclined at the hinder part, while the front is kept cool, hardly any tar is produced. The gas which collects above the oil in B passes on through the tube, C. The objections to the use of metallic vessels in distilling coal, are not applicable to the distillation of oils; and cast-iron vessels are, therefore, always employed, and heated over a furnace constructed in the usual manner. According to trustworthy statements, one cubic foot, or about four gallons of oil, produce six hundred to seven hundred cubic feet of gas, which is equivalent to from ninety to ninety-six per cent. of the weight of the oil; the remainder—excepting some unavoidable loss—consists of carbon, which is deposited upon the coke or bricks. According to Dr. FYFE, a gallon of oil seldom yields one hundred cubic feet of gas of good quality, on a large scale. That made at Leith, and in private gas-works at Edinburgh, had a specific gravity of from six hundred and forty to seven hundred and ten, containing matter condensable by chlorine. In this manufacture, about one half only of the oil is converted into gas. The production of oil-gas is a continuous process, and thus differs from the distillation

of coal. The retorts only require opening now and then, for the removal of the deposit of plumbago. Vapors of the same composition and properties are found in oil and coal gas. Thus, according to HESS, all the volatile empyreumatic oils, which occur mixed with each other in the tar from oil, have the same composition per cent. as olefiant gas. In the oil-gas made in England, and submitted to a pressure of twenty or thirty atmospheres, in order to render it portable, FARADAY observed that seven thousand five hundred volumes of gas were converted into one volume of fluid; and among the oily bodies, of which the liquid is composed, and which contain from eighty to ninety per cent. of carbon, this chemist was enabled to study some in an isolated state, as triyl— C_3H_3 , ditriyl— C_2H_4 —and a third hydrocarbon— C_2H_5 .—*Knapp.*

Gas from Soap-Water.—A favorable idea of the practical value of chemical knowledge is afforded by the process carried out at the works of HOUZEAU-MUIRON at Rheims, where very good gas and a handsome profit are obtained from a substance which had previously been a source of expense to the manufacturer to get rid of it. This refuse is the soap-water in which woollen stuffs have been freed from fat. Besides the unchanged fat with which the goods are charged as they come from the loom, the soap-water contains a solution of oleate and stearate of soda, and compounds of the same acids with lime in suspended flakes, and, lastly, animal matter extracted from the wool. From all parts of the town the soap-water is collected, and brought to the reservoirs of the works, where three hundredweight at a time are treated with two per cent. of sulphuric acid, or twice as much hydrochloric acid, mixed with an equal quantity of water. After the lapse of twelve or eighteen hours, the water is found to contain GLAUBER'S salt or sulphate of soda in solution, a little gypsum being formed at the same time, while an impure grey fatty matter rises to the surface. This consists of the fatty acids, oil, and animal matter mixed with water, the greater part of which having already been mechanically separated, the remainder is removed by melting the fat in a copper vessel, and ultimately drawing it off into a second boiler containing some sulphuric acid, for clarification. The filtration which follows affords a clear oil, and this gives with crude soda—containing sulphide of sodium—a very tolerable soap, whilst sulphide of iron separates, leaving a black solid residue containing much fat for distillation in the retorts. The process of distillation is similar to that practised with resin; the tar produced the first day is used on the morrow to dissolve and liquify the solid residue. The soap-water is obtained at the rate of ninepence for every thirty gallons.—*Knapp.*

Hydrocarbon Gas from Boghead Cannel.—The following interesting account of hydrocarbon gas from Boghead cannel, is adapted from an article in the *Journal of Gas-lighting*, from the pen of Dr. FRANKLAND of Manchester:—In the summer of 1851, this excellent chemist made an extensive series of experiments on the manufacture of hydrocarbon gas from cannel coals, in which the results obtained by WHITE'S

process were compared with those yielded by the usual method of gas-making. The experiments were made on a manufacturing scale, the cannels being worked in one hundredweight charges, in diaphragm retorts of the \square shape, six feet long, one foot six inches high, and one foot wide. The condensing and purifying apparatus was of the ordinary description, and the gas was passed through a station-meter immediately previous to its entrance into the holder, and at a temperature rather below than above that of the atmosphere.

Instead of receiving the whole of the gas in a large holder, and then experimenting upon the total quantity, FRANKLAND preferred, for certain reasons connected with the apparatus then at his disposal, to receive a portion only of the gas in a smaller holder, which was placed close to the meter, and received its supply through a very short three-fourths of an inch pipe from the main entering the meter. This small holder was capable of containing eighty cubic feet, and the flow of

gas into it was continuous throughout the whole process, and accurately regulated by a graduated stopcock, so as to allow the admission of a certain per centage throughout the entire working; for instance, if a ten per cent. sample was being taken, ten feet entered this holder during the time that ninety feet passed through the large meter. He had previously satisfied himself that, by attending to certain precautions mentioned below, this method furnished a perfectly fair sample of the total gas produced.

The results proved, in favor of the hydrocarbon process, a gain of from 45.8 to 290.6 per cent. in quantity of gas, and from 11.2 to 108.6 per cent. in total illuminating power, according to the quality of the cannels used. This gain in the total quantity of light yielded by a given weight of cannels, was also very remarkably corroborated by the analytical estimation of the value of the illuminating hydrocarbons in each gas, as is seen from the following summary:—

	Boghead.		Leemahagow.	Methel.	Wigan, Incehall.	Bulcarras.	Ramsey's Cannel.
	1st Exp.	2nd Exp.					
Per centage gain in illuminating power by hydrocarbon process,	88.4	82.4	82.8	108.6	33.9	42.4	11.2
Per centage gain in hydrocarbons expressed in their equivalents of olefiant gas,	83.9	..	85.1	109.2	34.0	..	11.3
Per centage gain in quantity of gas,	188.2	290.6	174.8	176.2	47.9	48.5	45.8

Subsequently, Dr. FYFE also made an extended series of experiments on the same subject; confining his attention, however, to the Boghead cannels, which, he justly remarks, is best fitted for testing the value of the hydrocarbon process. His results differ most widely from FRANKLAND'S, exhibiting invariably a loss of light—sometimes small, at other times enormously great—by the application of the hydrocarbon process.

Dr. FYFE'S experiments were conducted upon a very small scale—small \square -shaped retorts, two feet six inches long, and nine inches wide, being used, whilst the largest charge of cannels was seven pounds, and even still less quantities were frequently employed. They further differed from FRANKLAND'S trials in the whole of the gas being simultaneously received in two holders, so that the subsequent experiments upon it were conducted upon the total quantity of gas produced; whilst, in Dr. FYFE'S trials, a per centage only of the gas was received and submitted to experiment. To this latter circumstance mainly, Dr. FYFE ascribes the discrepancy in the results.

For some months after the publication of Dr. FYFE'S trials, Dr. FRANKLAND was residing on the Continent; and, for a long period after his return, the want of a suitable apparatus, and the little time at his disposal for such matters, prevented a repetition of the experiments upon Boghead cannels, in order to determine the accuracy or fallacy of former conclusions.

The appearance of another article, however, on the same subject, by Dr. FYFE, in the *Journal of Gas-lighting*, for March 1854, confirmatory of his previous results, determined Dr. FRANKLAND at once to institute new experiments, with an apparatus in which the total quantity of gas could be operated upon.

The apparatus employed consisted of a cannels retort

of the same size as that used in former experiments, surrounded by four water retorts, each of the same length as the cannels retorts, and nine inches in diameter, furnished with a diaphragm in the usual manner. The gas passed from the retorts through the hydraulic tubular condenser, and small wet and dry lime purifiers, to a station-meter, and thence to the holder, where the whole quantity produced in each case was received.

Although two hours were considered amply sufficient for complete intermixture and diffusion of the gases in such a holder, yet an interval of twenty-four hours was in each case allowed to elapse before the gas was submitted to the photometrical experiments. In thus using a large holder, it is indispensable that the gas for the illuminating room should be drawn directly from the water itself, and not from the large outlet-pipe, the unknown contents of which would, in many cases, supply a burner for several hours. This was effected by attaching a flexible tube to an aperture in the crown of the holder, and then conducting the gas to the illuminating room by a half-inch iron pipe. In this manner, a fair sample of the gas in the holder was secured. In all the experiments, the modification of BUNSEN'S photometer, by Messrs. CHURCH and MANN, was employed. The gas was consumed in fish-tail and Winfield burners; and, in every instance, the determination was made when the gas appeared to be burning to the best advantage. The numbers obtained were, as usual, corrected to the one hundred and twenty grain candle standard.

Having previously ascertained that Boghead cannels, when distilled alone, yields considerably higher results in small quantities, and being desirous of placing the cannels in the best possible position for a comparison.

only half a hundredweight was used for each experiment, in place of one hundredweight, as employed in previous trials. In making the hydrocarbon Boghead gas, the evolution of water gas was so managed, that the mixture of gases generated throughout the entire working was maintained at a nearly uniform illuminating power. To do this, the generation of water gas must at first be very rapid, and should nearly cease at the end of the second hour. The heat was a good bright red; and, in the trial with Boghead alone, it was slightly higher than in that with Boghead and water.

The following results were obtained:—

I.—BOGHEAD WITHOUT WATER GAS.

Cannel used, Fifty-six pounds.
Gas produced, Three hundred and sixty-four cubic feet.
Time occupied, Two hours and forty-five minutes.
Gas per ton, { Fourteen thousand five hundred and sixty cubic feet.

ILLUMINATING POWER OF GAS.

Two cubic feet per hour, fish-tail No. 1. Candles.	Three cubic feet per hour, fish-tail No. 2. Candles.	Four cubic feet per hour, fish-tail No. 3. Candles.	Five cubic feet per hour, Winfield's burner. Candles.
14.7	25.5	36.4	48.9

ILLUMINATING POWER OF ONE CUBIC FOOT OF GAS.

Candles.	Candles.	Candles.	Candles.
7.35	8.5	9.1	9.78

Illuminating power of total gas, when burnt at the rate of three cubic feet per hour, = 309.4 sperm candles, each sperm candle burning ten hours, at the rate of one hundred and twenty grains per hour.

II.—BOGHEAD WITH WATER GAS.

Cannel used, Fifty-six pounds.
Gas produced, Nine hundred and four cubic feet.
Time occupied, Two hours and forty-five minutes.
Gas per ton, { Thirty-six thousand one hundred and sixty cubic feet.

ILLUMINATING POWER OF GAS.

Two cubic feet per hour, fish-tail No. 1. Candles.	Three cubic feet per hour, fish-tail No. 2. Candles.	Four cubic feet per hour, fish-tail No. 3. Candles.	Six cubic feet per hour, Winfield's burner. Candles.
11.1	1.90	26.9	48.1

ILLUMINATING POWER OF ONE CUBIC FOOT OF GAS.

Candles.	Candles.	Candles.	Candles.
5.35	6.33	6.72	8.0

Illuminating power of total gas, when burnt at the rate of three feet per hour, = 572.5 candles. Hence, gain in illuminating power by employment of water gas, per ton, = 10,524 candles; 85.0 per cent. Gain in quantity of gas, = 21,600 cubic feet; 175.9 per cent.

These results, therefore, most satisfactorily confirm those obtained in former experiments, *vide* *supra*:—

	Per Ton.		Per Cent.	
	1st Experiment.	2d Experiment.	1st Experiment.	2d Experiment.
Gain in illuminating power by employment of water gas,	10,028 candles.	9,348 candles.	88.4	82.4
Gain in quantity of gas,	24,920 cubic feet.	38,480 cubic feet.	188.2	290.6

Thus showing that experiments, in which a certain per centage only of the total gas generated is operated upon, are worthy of full reliance if conducted with the necessary precautions; but, in order that the results may be received with the same confidence, FRANKLAND admits that this method requires more faith in the manipulatory skill of the operator than the other; for, as Dr. FYFE has shown, it is easy to commit very serious errors if the necessary precautions be not attended to. The essentials to accuracy are—first, that the tube supplying the small holder from the main should be as short and narrow as practicable; secondly, the gas should be admitted into the small holder *continuously* throughout the entire working, and not in isolated portions at stated periods; and, thirdly, the sample thus taken should not bear too small a proportion to the total quantity of gas generated. In FRANKLAND's former experiments all these conditions were secured; but in the trial quoted by Dr. FYFE, in which the sample collected in the small holder was thirty-three per cent. worse than it ought to have been, they were disregarded. In Dr. FYFE's experiments, the capacity of the inlet-pipe was one hundred and thirty-two cubic inches, the gas was received in isolated portions at stated periods, and the sample thus collected bore a relation to the total gas of only 1 : 500. In FRANKLAND's experiments, the contents of the inlet-pipe were only eighty-three cubic inches; the sample was collected continuously, and in the three experiments on Boghead cannel, it bore relation to the total gas:—

First Experiment,	1 : 8.3
Second Experiment,	1 : 23.8
Third Experiment,	1 : 32.3

These considerations clearly point to the causes of

the discrepancy observed by Dr. FYFE in his small per centage sample; and as the results of FRANKLAND's second series of experiments, made with all the precaution which Dr. FYFE considers necessary to accuracy, coincide closely, as seen above, with those he already published,—the actual gain of light per ton, ten thousand five hundred and twenty-four sperm candles, being somewhat greater than the mean of the first series, nine thousand six hundred and eighty-eight, and the per centage gain eighty-five,—it now only remains to show the cause of the discordance between Dr. FYFE's experiments and his—the one assigned by Dr. FYFE, viz., the use of a per centage sample, being completely disproved.

In pointing out what FRANKLAND conceives to be the true cause of the discordance, attention will principally be confined to Dr. FYFE's last experiments, in which he used retorts of the customary size; because FRANKLAND is convinced that no results obtained with such a small apparatus, and such minute charges of cannel as those used in his first experiments, can be relied upon for comparison with experiments on a manufacturing scale. He feels also less reluctance in leaving these experiments out of consideration, since Dr. FYFE himself admits, to a certain extent, that they were made upon too small a scale to be depended upon. For the hydrocarbon process especially, retorts of such small *longitudinal* dimensions are peculiarly unfitted; because the amount of carbonic acid generated in the water retort is greatly augmented by diminishing the length of charcoal surface over which the water gas has to travel, and, for the same reason, a great excess of steam is also very liable to pass into the coal retorts, thus damaging the luminiferous constituents there gene-

rated. In addition to this cause of error, the experiments in question must have been much vitiated by the rapid carbonization of the very small quantity of cannel used, nearly the whole of the gas from which would certainly be expelled in thirty minutes—a length of time far too short for the generation of the requisite quantity of water gas from one small retort.

In Dr. FYFE's last experiments, he used two retorts of a large size, one containing the charcoal or coke by which the water was decomposed, the other the coal, of which two hundredweight were used in each charge. Two charges were worked off, both with water gas, and the gaseous products received in a large holder. The average of these trials was twenty-seven thousand cubic feet per ton, yielding light equal to 2830·15 pounds of sperm. Dr. FYFE then compares this result with that which he obtained by working the seven pound charges above alluded to, and thus shows a loss of thirteen per cent. by the hydrocarbon process.

The two principal points, in which the conclusions drawn by Dr. FYFE from these results differ from FRANKLAND's, are—first, his high estimate of the powers of the Boghead cannel distilled alone; and, secondly, the comparatively low results which he obtained by the collateral use of water gas. The first of these points arises, as just mentioned, from reliance being placed upon certain results obtained in small retorts with seven pound charges of cannel, which results differ most widely from those of all other experiments, as also from the previously published report of Dr. FYFE himself.

To determine the influence of small charges in increasing the yield and the illuminating power of the gas from Boghead cannel, FRANKLAND put 2·5 ounces of the same sample as that used in his last experiments in a hand glass tube; it gave 1·88 cubic feet of gas, five feet per hour of which yielded a light equal to 64·5 candles. These numbers are equivalent to fifteen thousand four hundred and eighty-two cubic feet per ton, or 3423·7 pounds of sperm per ton—a result which even exceeds that of Dr. FYFE, and shows how little dependence can be placed in experiments upon small quantities of this cannel.

It is, therefore, greatly to be regretted, that Dr. FYFE did not, at the time of making his last experiment at Leith, try a corresponding one with Boghead cannel alone in the same apparatus, instead of continuing to quote the results of his former trials on the small scale, which he admits to be unworthy of full confidence. Had he done so, FRANKLAND feels assured that he would have removed one cause of discrepancy—*videlicet*, his estimate of the value of Boghead cannel when distilled alone, which, as proved, is far too high.

Dr. FRANKLAND acknowledges himself indebted to Mr. A. WRIGHT and Mr. T. G. BARLOW of London, and to Mr. A. KING of Liverpool, for some very important information on this subject—the first gentleman having tested the value of the Boghead cannel during several weeks' working on a very large scale, and the latter two having made a very extensive series of most careful experiments upon a small scale. In Mr. WRIGHT's experiment, three parts of Newcastle coal—Dean's Primrose—and one part of Boghead can-

nel, were distilled in separate retorts, yielding nine thousand five hundred cubic feet per ton; the mixed gases were burnt in a Number 2 fish-tail burner, 2·5 feet per hour giving light equal to thirteen candles. From this result of the mixed gases, the value of the Boghead was calculated to be 5·44 times that of an equal weight of the Newcastle coal; and therefore, taking the well-known value of Newcastle coal at nine thousand feet per ton—five feet per hour = thirteen candles—it follows that a flame of Boghead gas burning five feet per hour would give a light equal to 57·9 candles, at which rate of consumption the total gas from one ton of Boghead would be equal to 2182·1 pounds of sperm. Mr. KING's result is the average of eleven experiments, each made upon the one-thousandth of a ton; the gas was burnt by a Number 1 fish-tail burner, at rates of consumption varying from 1·38 to 2·04 feet per hour. The value assigned by Mr. BARLOW to Boghead is the average of three experiments, which were also made upon the one-thousandth of a ton of cannel, the gas having been burnt at the rate of from 1·44 to 1·92 feet per hour. If, in the experiments of Mr. KING and Mr. BARLOW, the gases had been burnt at higher rates of consumption, there is no doubt that the equivalent of sperm per ton would have been somewhat higher. In addition to this valuable evidence from gentlemen so intimately acquainted with the subject, there is also the statement of the owners of the cannel, contained in their advertisement, which appears monthly. FRANKLAND considers this statement as good evidence on one side of the question, inasmuch as it is not usual for merchants to underrate the value of the commodities they have to sell. These estimates, along with that contained in Dr. FYFE's printed report to the owners of the coal, are now appended with FRANKLAND's results:—

ESTIMATES OF THE VALUE OF BOGHEAD CANNEL.

Authority.	Cubic feet of gas per ton.	Gas from one ton, = 16 sperm.
Mr. Wright,.....	11,000	2182·1 pounds.
Mr. Barlow,.....	13,344	2057·0 “
Mr. King,.....	13,549	1993·6 “
Dr. Fyfe,.....	14,800	2283·2 “
Advertisement of proprietors of Boghead cannel,.....	13,500	1967·1 “
Dr. Frankland's 1st experiment,.	13,240	2387·7 “
Dr. Frankland's 2nd experiment,	14,560	2441·1 “

The above are by no means selected; they include all the experiments upon this cannel, with the exception of the subsequent ones by Dr. FYFE, to which allusion has already been made. It will be seen from this statement, that FRANKLAND's results are considerably higher than those of any other experimenter. This is ascribed to the use of a diaphragm retort, and he believes that it is impossible to obtain numbers so high as his in retorts of the ordinary construction. The relation of these numbers to those employed by Dr. FYFE for comparison with his experiments on the hydrocarbon process—namely, Dr. FYFE's results with seven pound charges, 16,093 cubic feet of gas per ton; gas from one ton = 3253·5 pounds sperm—must convince every candid mind that his results are far too high, and cannot fairly be quoted for comparison with any experiments on the hydrocarbon process.

Having thus obtained a basis of experimental results for comparison with those yielded by the same cannell when treated according to the hydrocarbon process, FRANKLAND proceeds to show the gain in illuminating power which that method exhibits, when the experiments upon it by Dr. FYFE and himself are compared with these several results; for Dr. FYFE rightly contends that it is to this test, and not to that of gain in quantity of gas only, that the hydrocarbon process must be submitted.

The comparison which FRANKLAND formerly published, as well as the one previously cited, were founded upon equal consumptions of the respective gases; but Dr. FYFE prefers to burn each gas to the best advantage, with a given burner—generally a Winfield—at high rates of consumption, and then to calculate the value of each cubic foot. By this

method, the comparison may be said to be nearly that of equal light, instead of equal consumpts. FRANKLAND and FYFE agree on this point, and think that the basis of comparison, especially in gases differing much in richness, ought to be that of equal lights and not of equal consumpts. By adopting this plan in the following comparisons, the former has been compelled, in the case of his second experiment, to calculate the hourly consumption of a flame giving a light equal to about fifty candles, as he made no experiment beyond twenty candles. A consumption of ten feet per hour in a Winfield's burner is estimated as being equal to the light of 50·6 candles of one hundred and twenty grains per hour. He does not insist upon the absolute correctness of the gain exhibited by his second experiment, although he believes it to be very near the truth:—

PER CENTAGE GAIN IN ILLUMINATING POWER BY THE HYDROCARBON PROCESS AS APPLIED TO BOGHEAD CANNEL.

Name of Experimenter on Hydrocarbon Process.	Comparison with results obtained with Boghead Cannel alone, by				Proprietor of Boghead Cannel.	Dr. Frankland's First Experiment.	Dr. Frankland's Second Experiment.
	Mr. Wright.	Mr. King.	Dr. Fyfe.	Mr. Barlow.			
Dr. Fyfe—experiment at Leith gas-works,	Per cent. 29·7	Per cent. 42·0	Per cent. 24·0	Per cent. 37·6	Per cent. 43·9	Per cent. 18·5	Per cent. 15·9
Dr. Frankland's first experiment,	89·6	107·5	81·2	101·1	110·3	73·3	69·5
Dr. Frankland's second experiment,	105·6	125·0	96·5	118·1	128·1	87·9	83·8
Dr. Frankland's third experiment,	127·7	149·2	117·6	141·5	152·6	108·1	103·6

These numbers prove, in the most incontestable manner, that there is invariably a very large gain by the employment of the hydrocarbon process, varying with the amount of water-gas used, and with the value at which the gas from Boghead alone is estimated. This gain is even apparent from Dr. FYFE's own experiments, although its smallness, in comparison with that exhibited by FRANKLAND's own trials, must strike every observer of the above table. The cause of this is, however, made clearly apparent when the mode in which Dr. FYFE conducted his is taken into account.

Dr. FRANKLAND has found that one water retort is incapable of generating more than one-half the amount of water-gas requisite for one hundredweight of Boghead cannell; and yet, notwithstanding this caution, Dr. FYFE carbonized two hundredweight of cannell with only one water retort; the water-gas power was, therefore, only one-fourth of what it ought to have been, and, as might naturally be expected, the gain was only one-fourth of that which a properly-conducted experiment would yield. The Editor considers that Dr. FRANKLAND has clearly demonstrated that there is a high gain in the total illuminating power obtainable from a given weight of Boghead cannell by the employment of the hydrocarbon process, and that his former estimate of that gain—at from eighty to ninety per cent.—was by no means too high. Since the publication of his first report on hydrocarbon cannell gas, he has had abundant opportunities of witnessing the working of the process; and although he admits that it is more liable to suffer from the carelessness of workmen than the old process, yet his confidence in its merits, and in its ultimate extensive adoption by gas engineers, continues in every respect unshaken.

Illuminating Power of Gases.—The illuminating power of gas, say RICHARDSON and RONALDS, has generally been estimated by the shadow-test, or by BUNSEN's photometer, in conjunction with an experimental meter for accurately measuring the consumption. The standard of comparison used by different experimenters has not always been the same; but a spermaceti candle, consuming one hundred and twenty grains per hour, is now generally adopted.

Illuminating gas must vary in its power of giving light according to the proportion of carbon it contains; but much depends upon the mode of combination in which this element is present, and also upon the manner in which the gas is burned. Thus, carbon, in the form of carbonic acid, is not only useless as a source of light, but actually prejudicial, a very small proportion of carbonic acid in coal-gas reducing the illuminating power to a great extent. Carbon, in the form of carbonic oxide, and as light carbide of hydrogen, is of little or no value as a source of light, these gases burning with a very faint flame. The heavy carbide of hydrogen, as olefant gas, oil-gas— C_8H_8 —and the vapors of naphtha, many and indeed most of which are condensed by chlorine, bromine, and anhydrous sulphuric acid, are the ingredients of coal-gas to which it owes its illuminating power. Hence the value of gas as an illuminating agent has been frequently estimated since the time of HENRY, by the amount of condensation which it undergoes when mixed with a sufficient quantity of chlorine to absorb these higher compounds of carbon with hydrogen. Dr. FYFE relies most implicitly upon the condensation test by chlorine, in connection with what he terms durability, for an accurate indication of the value of any gas; and he has shown, in a great many

instances, that these two points give a value which agrees very well with carefully-conducted photometrical experiments. By durability, is to be understood the time during which a certain volume of gas will continue to afford a standard amount of light. Bromine is employed by many to replace the chlorine in condensing the heavy carbo-hydrogens, and is, in many respects, more convenient for manipulation. In both cases, the vapors of these substances left after condensation require to be removed from the gaseous mixture by a solution of potassa before the amount of condensation is estimated. Anhydrous sulphuric acid, obtained by warming the Nordhausen acid, is preferred by others for effecting this condensation, a ball of porous coke attached to a platinum wire being saturated with the acid and thrust up into the mixture of gases. The substances condensed from the gas by all these agents appear to be the same; but from what has been stated with reference to the nature of these condensed hydrocarbons from different specimens of coal-gas, the illuminating power of the gas must depend far more upon the chemical constitution, and upon the amount of carbon which they respectively contain, than upon the volumes which they occupy before condensation; and hence, although the test may be a good one, obtained from the same species of coal under like conditions, and containing the same kinds of hydrocarbons, it is not applicable as a means of setting a value upon gases obtained under different circumstances from different species of coal.

The substances condensed by these re-agents are probably similar, if not identical, in composition with those condensed from oil-gas and resin-gas. It has been ascertained, by comparing the density of ordinary Newcastle coal-gas before and after condensation by bromine, that the vapors of the light-giving portions give a specific gravity ranging from 2·8 to 3·3.

The liquid condensed from resin-gas by Mr. COUERBE yielded six fluids, the nature of which, with the calculated and experimental density of their vapors, are given in the following table:—

No.		Density of Vapor.	
		Calculated.	Found.
1.	C ₄ H ₄	1·763	2·000
2.	C ₅ H ₄	2·385	2·254
3.	C ₆ H ₄	2·806	2·802
4.	C ₇ H ₄	3·230	3·340
5.	C ₈ H ₄	3·660	3·765
6.	C ₂₅ H ₂₂	2·665	2·637

The first of these has a specific gravity about equal to the condensable matter in Wigan cannel and Ramsey's cannel, while the third and fourth resemble that from Pelaw, Pelton, and other Newcastle coals. A more elastic vapor probably remained in the gas from which these substances were condensed, which would have a lower specific gravity, and come to resemble the condensable matters and Lesmahagow cannel-gas. The specific gravity of the condensable matter from these gases may be seen from the annexed table by Mr. EVANS of the Westminster Gas Works, taken from the *Journal of Gas-lighting*:—

Name of Coal.	Gas per ton.	Condensed per cent. by bromine.	Specific gravity of gas.	Specific gravity of condensed matter.	Photogenic Power.	
					Actual.	By analysis.
Boghead,.....	15,000	30·	·752	1·21	37·75	36·3
Lesmahagow, No. 1,.....	13,500	16·	·642	1·64	27·1	26·24

West Hartley,.....	10,500	12·5	·420	4·2
Hastings Hartley,.....	10,300	12·5	·421	4·3
Blenkinsop,.....	9,700	14·	·450	6·

The only sure method of arriving at the actual

amount of carbon in a gaseous mixture, and at the same time showing the character of the carbonaceous compounds contained in it, is to combine the condensation method with an organic analysis, or by the old plan of combustion with oxygen, as proposed by HENRY, noting the quantity of oxygen consumed, and the amount of carbonic acid produced. Thus, a known volume of coal-gas is mixed with an excess of oxygen and exploded, the amount of carbonic acid produced and of oxygen consumed being ascertained. Another equal volume is then treated with an absorbent, as anhydrous sulphuric acid, and after all the residue is again mixed with oxygen, and exploded; the amount of carbonic acid being again ascertained, and deducted from the quantity obtained by exploding the original gas. The quantity of carbon contained in the condensed portion of the gas being thus ascertained, its value as an illuminating agent may be calculated accordingly. There appear to be some compounds of

carbon and hydrogen in certain coal gases different from light carbide of hydrogen, and which are not condensed by any of the absorbents named, and which, nevertheless, add much to the illuminating power; so that calculations based upon the above method of analysis will prove rather below than above the true value of the gas.

In estimating the value of gases by the photometer, it is absolutely necessary to burn the gas in a great variety of ways—with differently constructed burners, in different quantities, and under varying amounts of pressure—in order to ascertain under what conditions it affords its full value as an illuminating agent. A gas which is very rich in heavy hydrocarbons cannot be burned to advantage with a burner adapted for less rich gas—the apertures require to be smaller, in order to bring more oxygen into contact with each flame; and a poor gas, on the contrary, burned in a manner suitable for rich gas, will not afford its maximum effect, in consequence of too much air being brought into contact with the flame.

If the central ring of an argand burner, consuming oil without smoke at its maximum degree of brightness, be closed so as to exclude the inner current of air from the flame, the brightness is visibly diminished, but, strange as it may appear, the amount of light, as indicated by the photometer, is increased. A greater number of the particles of carbon are rendered luminous before being consumed, by diminishing the supply of air in this manner, and a greater quantity of light diffused, although the light is not so brilliant. By increasing the supply of air, much of the carbon is consumed at once, without taking a solid form in the flame; more heat is then produced, and those particles which are solid in the flame are more intensely heated: quantity of light is then sacrificed to intensity. Gas has little tendency to smoke. It is generally better suited to the production of intensity than quantity of light; and for this reason, in comparing the illuminating power of different gases with each other, it would be better to adopt as a standard the flame of some gaseous mixture of known composition, instead of the spermaceti candle, which is calculated for affording quantity rather than intensity of light.

The more carbon there is contained in gas the heavier it is, and specific gravity has, therefore, been often resorted to, as an indication of the relative value of different gases. If carbonic acid has been completely separated, and no excess of carbonic oxide is present, the specific gravity may furnish an important indication to the manufacturer of the value of gas made under similar circumstances; but it can never replace an analysis in judging of the value of different gases, as the amount of carbonic oxide will vary with the kind of coal used, and the method of conducting the distillation, the specific gravity of which is very nearly equal to that of olefant gas.

Mr. WRIGHT employs a small balloon, capable, when filled, of holding one thousand cubic inches of gas, which is gauged by a ring fitting its largest diameter when full. The weight of the balloon and car being known, and the air expelled, it is filled with gas; weights are then placed in the car until it remains

in equilibrium in the air. The data thus obtained, with corrections for temperature and pressure, afford an approximate means of ascertaining the specific gravity of the gas. Mr. WRIGHT has constructed a table, by simple reference to which, and a knowledge of the weights required to balance the balloon, the specific gravity may be read off for any variations of temperature and pressure. Little reliance is, however, placed by gas engineers upon any test of illuminating power based upon specific gravity, as this is often considerably increased by the presence of carbonic acid and carbonic oxide, which add to the weight without increasing the illuminating power of gas.

CHRISTISON and TURNER observed the following relations between the specific gravity and illuminating power of coal and oil gas:—

Specific gravity.		Relation of Illuminating power.	
Of Coal-gas.	Of Oil-gas.	Of Coal-gas.	Of Oil-gas.
0.659	0.118	100	140
0.578	0.910	100	225
0.605	1.110	100	250
0.407	0.940	100	354
0.429	0.965	100	356
0.508	1.175	100	310
0.529	0.986	100	272 average.

According to a report made by HEDLEY to Parliament, the illuminating power of coal-gas, in twelve principal districts of England, amounts to between 4.408 and 1.645 times that of a tallow candle—six to the pound; but ordinarily about two or three times, when the consumption varies from 2.3 to 1.5 cubic feet per hour, and the specific gravity from 0.58 to 0.412.

With the same burner and gas, the amount of light depends upon the height of the flame, which practically, the pressure being nearly constant, is regulated by the position of the cock, or by varying the size of aperture in the burner. According to CHRISTISON and TURNER, the advantage increases with the height of the flame, but to a limited extent only, and for a simple jet in the following proportion:—

Length of the flame in inches.	Intensity of the light from equal quantities of		Coal-gas.		Oil-gas	
	Coal-gas.	Oil-gas.	Intensity of the light.	Gas consumed.	Intensity of the light.	Gas consumed.
1	—	100	—	—	22.0	33.1
2	100	122	55.6	60.5	63.7	78.5
3	109	159	100.0	101.4	96.5	90.0
4	131	181	150.0	126.3	141.0	118.0
5	150	174	197.8	143.7	178.0	153.0
6	150	—	247.4	182.2	—	—

Thus the point at which further advantage ceases to result on raising the flame of oil-gas is four inches, whilst for coal-gas it is five inches, which in general requires the flames to be higher. The consumption of gas and the intensity of the light increase together, but the latter in a more rapid ratio up to a certain point. This occurs to a still greater extent with argand burners, for which, with the same consumption of gas, these observers found the intensity of the light to be,—

100 282 560 582 582 504
At a height of 0.50 1 2 3 4 5 inches.

According to FYFE's experiments upon different burners, in which he probably used a better kind of coal-gas, the increase is as follows:—

With twenty-four apertures of one-fortieth of an inch, the diameter of the perforated ring being seven-eighths of an inch,..... 100 121·8 — 188·5 — 236·6 — 235·4
 With forty-two apertures of one-fiftieth of an inch, the ring being twenty-one twentieths of an inch in diameter, 100 136·6 — 176·2 — 194·8 — 242·3
 Height in inches,... 1 1·5 1·75 2 2·5 2·75 3 3·5

Lastly, his experiments gave a view of the intensity of the light produced by the same quantity of gas in different burners, when separately compared at the most advantageous height of the flame:—

Burners.	Bat's-wing.			Argand burners.		
	Simple Jet.	Small.	Large.	Fish-tail burner.	With 24 holes.	With 42 holes.
Quantity of light from the same amount of gas, }	100	135	164	138	183·5	182·3

According to the observations of HEDLEY, already quoted, which were made in the gas-works at Sheffield, the intensity of the light of a simple four-inch jet is to that of a 3·5 inch argand flame—from fourteen apertures—as 1 : 4·4 to 4·8, the amounts consumed being as 1 : 3 cubic feet, which corresponds to a greater amount of light from the argand burner by from 1·47 to 1·6 for the same quantity of gas. From the general report of the same engineer upon the principal gas-works in England, it is found—in the case of coal-gas—the average specific gravity being 0·476, that a simple jet, four inches in height, consumes on the average one cubic foot per hour.

The superiority of the flat flames over the simple round ones, explains an observation which has been made with regard to the argand burners. When the apertures in it are placed so far apart as to form a circle of distinct jets, the effect is one-third weaker, with the same current of gas, than when the jets—of one-sixth, to one-eighth of an inch—unite into a single flat ring.

The subjoined experiments on the illuminating power of Wigan canal-gas with different burners have been recorded by Mr. ALFRED KING:—

	One-half foot.	One foot.	One and a half feet.	Two feet.	Two and a half feet.	Three feet.	Three and a half feet.	Four feet.	Four and a half feet.	Five feet.	Five and a half feet.

The following experiments upon the illuminating power of Newcastle cannel-gas, were made by Mr. WRIGHT with the burners used in London for consuming that kind of gas:—

The No. 1 Scotch fish-tail gives a flame fully spread with .85 inch pressure, and when burning at the rate of 1.4 feet per hour, beyond which point it begins to show streaks of blue.

The No. 2 Scotch fish-tail is fully spread with .9 inch pressure, and when burning at the rate of 2.4 feet per hour.

GUISE's burner is an argand with twenty-six holes, the inner diameter of the ring being six-tenths of an inch, and the outer nine-tenths of an inch. It has a metal button, five-tenths of an inch diameter, one inch above the face of the burner. The glass chimney is a

straight cylinder, two inches diameter and six inches long.

With a three-tenth inch pressure, and a consumption of 4.5 feet per hour, the flame becomes irregular, and has a tendency to deliver smoke.

The standard candle used by Mr. WRIGHT consumed one hundred and thirty grains per hour, and for this, to insure a greater regularity of flame, a No. 2 fish-tail, burning .4 feet per hour, was substituted, and found exactly equal to the candle.

In the first of the following tables, the results are multiplied by one hundred and thirty, and divided by one hundred and twenty, so as to reduce them to a standard candle of one hundred and twenty grains per hour, as done by Mr. KING:—

Consumption per hour.	One foot.	One and a half feet.	Two feet.	Two and a half feet.	Three feet.	Three and a half feet.	Four feet.	Four and a half feet.

Mr. BARLOW has recorded some experiments made by him with different burners on gas manufactured from a mixture of Pelton, Felling, and Dean's Primrose, all first-class Newcastle gas coals, the average produce being eight thousand five hundred feet per ton of coal. The burners he used were:—

1st. A Number 3 fish-tail, or union jet.

2nd. A Number 5 bat's-wing.

3rd. A common argand, with fifteen large holes in a ring .85 inch diameter, and a cylindrical chimney-glass 7 inches high.

4th. A Platow's registered argand, with large holes

in a ring .9 inch diameter, with inside and outside cone, and cylindrical chimney-glass 8.5 inches high.

5th. A Bizner's patent Number 3 argand, with twenty-eight medium-sized holes in a ring .75 inch diameter, and cylindrical chimney-glass 8.65 inches high.

6th. A Winfield's registered argand, with fifty-eight medium-sized holes in two rings of twenty-nine holes in each, the mean diameter being one inch, with deflecting button inside and gauze below; bellied chimney-glass eight inches high.

7th. A Leslie's patent argand, with twenty-eight jets

in a ring .95 inch diameter, and chimney-glass 3.5 inches high.

8th. A Guise's registered shadowless argand, with twenty-six large holes in a ring .85 inch diameter, and deflecting button; cylindrical chimney-glass 6.1 inch high, and glass reflecting cone to outside gallery.

On an average of numerous trials the annexed results were obtained:—

SERIES NO. I.				
Burner.	Consumption per hour.	Value of one cubic foot in grains of spern.	Standard candles per cubic foot.	Value of eight thousand five hundred feet of gas in pounds of spern.

No. 8,....	5.5	364.	3.03	442.

It is quite evident from these experiments that the No. 6, or Dr. Fyfe's Aberdeen argand, required a longer consumpt than 5.5 feet per hour to bring out the full effect of Newcastle coal-gas of the quality used in this case, for, when the consumpt was increased to 6.5 feet per hour, it gave results equal to any of its compeers at 5.5 feet. No. 2 and No. 7 burners were tried with the utmost quantity which could be consumed in them without smoking or burning advantageously.

Though these experiments indicate the relative adaptation of the several burners for the combustion of Newcastle coal-gas, they must not be taken as settling the question of the practical value of each. Some of them cast shadows, which detract considerably from the light they yield when placed above the level of the eye; this is particularly the case with No. 5, which otherwise gives the best results. Others, like No. 7, require a perfect uniformity of pressure, and an absence of all currents of air. Taking all things into consideration, No. 8 is, perhaps, the one to which these objections least apply, and it gives the next largest amount of light for the gas consumed, though the slight advance upon the old argand, as constructed twenty-five years since, cannot fail to be remarked.

Glass chimneys are not so requisite for gas as for lamp flames, and their effect is quite different from that exerted upon the wick flame of a lamp. The jet of gas, as it leaves the burner, is in far more correct relation to the air, than is the case with the gas produced at the burning margin of the wick.

Argand wick flames require a strong draught, and never burn without smoke, unless a chimney is used; with gas flames, the glasses are used rather to steady the flame than to insure its perfect combustion: they are always made shorter than the glasses of oil-lamps. If too high chimneys are used, the draught of air soon cools the base of the flame, and the air becoming mixed with the gas, a diminution of the light results,

which is caused by the combustion of too much carbon simultaneously with the hydrogen; hence but little is momentarily separated in the flame. A striking proof of this is afforded by the well-known experiment, in which a closed cylinder of wire-gauze, through which flame cannot be communicated to a combustible mixture, is adapted to a gas-burner. The jet of gas which, without the case of wire-gauze, yields a perfect flame, becomes intimately mixed with air in the interior of the case, and on its exit burns with a pale blue light, because the separation of carbon in the flame no longer occurs, both carbon and hydrogen being burnt simultaneously. This experiment gives an important hint on the general management of the draught in illumination. The same result may be observed when the gas is allowed to escape with too great velocity; and, if the proper limit is exceeded, the flame may be extinguished by being too much cooled: with a certain velocity, the current will not ignite for a distance of several lines from the aperture, and then burns with a faint blue flame, the gas having become mixed with air.

It is by taking advantage of this effect of a strong current of air, that the highly carbonaceous vapors of oil of turpentine, coal-tar naphtha, and similar substances, may be burned without smoke, as in BUSSON and ROUEN'S apparatus, or in HOLLIDAY'S lamps. The oils being allowed to escape in the form of a jet of vapor, under a pressure varying, according to circumstances, from four to twenty-four lines of mercury, the excess of carbon is brought to a proper proportion by the admixture of air, without interference with the order of combustion. In this manner brilliant flames, free from soot, are produced.

Among the arrangements which increase the light by raising the temperature of the air, the burner invented by M. PARISOT of Paris is distinguished by its simplicity and great facility of construction. It admits the air by narrow passages between two thick concentric cylinders or cones, about four inches in height. The gas escapes by a circular slit, easy to clean. This burner gives a full light and a very steady flame.

Application of Gas as a source of Heat.—Gas has long been employed as a source of heat in chemical and pharmaceutical laboratories, but it is only during the last few years that it has been more extensively used for cooking, warming apartments, *et cetera*.

Comparison of the various methods of Illumination with each other.—In the foregoing remarks, the relative illuminating values of the various methods of producing artificial light have generally been shown, without reference to the cost of the light. This still remains to be considered, in order to estimate their relative economy. PECKET, in the following sketch, has in each case taken the cost into account; but this will vary with the rise and fall of markets, and with the locality. The price of a pint of oil—0.9 lb.—is here fixed at about fivepence; of one pound of tallow candles at sevenpence, wax candles at two shillings and twopence, stearin candles at one shilling and fourpence; a pint of illuminating spirit—0.8 lb.—at eightpence; of one hundred cubic feet of coal-gas at sevenpence; and lastly, of one hundred cubic feet of oil-gas at two shillings and threepence.

Means of Illumination.	Intensity of the light.	Consumption of illuminating material per hour.	Illuminating power, Carcel's lamp = 100.	Price of 100 grammes of illuminating matter.	Cost of the light per hour in pence.	Cost of a light of the same intensity per hour in pence.

Oil-gas,	127·00	2·43		19·2	0·630	0·367

The light of wax candles is the most expensive, then that of stearin candles and the vapor lamp, which are also costly. There are, however, few instances in which public opinion and scientific estimation of the value of an article are so much at variance as with reference to the means of illumination in general; occasional deceptions, such as occur in the lamp of BENKLER, not being taken into consideration. A glance at the last column in the above table shows that the modes of illumination which, on account of their supposed cheapness, are partly used by the wealthy and exclusively by the poor, are those which—excluding

articles of luxury, such as wax, *et cetera*—cost most in producing a certain degree of brilliancy. A given amount of light yielded by tallow candles costs from three-fifths to twice as much as when it is obtained from the lamp of CARCEL; with the kitchen lamp it costs nearly three times, and by the lamp with the flat wick more than twice as much.

The more ordinary light-giving materials have recently been examined, and compared with the light obtained from what is called common or thirteen-candle coal-gas. Tried by the photometer:—

One thousand cubic feet of gas were found equal to the light of 312,000 grains, or 44½ pounds of sperm candles.	
" " " " 341,750 " 48½ pounds of carefully-snuffed wax candles.	
" " " " 358,000 " 51½ pounds of stearic acid candles.	
" " " " 370,540 " 52½ pounds of best mould candle.	
" " " " 381,000 " 54½ pounds of best dip candles.	
" " " " 417,220 " { 6½ gallons of purified colza oil, specific gravity 915.	
" " " " 366,310 " 5½ gallons of sperm oil, specific gravity 888.	

As the price of gas varies in different parts of the United Kingdom from four shillings and sixpence to ten shillings per thousand cubic feet, to obtain the relative cost it is necessary to multiply the prices of the other materials per pound with the numbers in the above table.

Thus, with gas at four shillings and sixpence per thousand cubic feet, and dip candles at sevenpence per pound, the cost of an equal amount of light from the two sources will be as four shillings and sixpence to one pound ten shillings and tenpence.

The great obstacles to the more general introduction of gas-light into private houses, are the difficulty of placing the light in such a position as to be available for all purposes, and that of reducing the consumption to the requirements of the consumer. A candle or a lamp can be placed wherever it is wanted, while a gas-light, even when flexible india-rubber tubes are used, is always more or less a fixture. The burners in common use are also calculated for giving more light than is required for one or two persons; and hence, though the light from gas is so very much cheaper, yet a larger quantity of light than is absolutely necessary being generally employed wherever gas is introduced, the

actual saving by its introduction is not so great as the difference of price in the light would make it appear.

The foregoing tables also show that the most economical light is obtained from the best constructed lamps, which, in addition to being costly themselves, also consume large quantities of oil, and are therefore not economical when used by a single person. There still appears much room for improvement in the adaptation of good lamps to the requirements of small consumers. A lamp which would give the light of one or two spermaceti candles, and yet be relatively as economical in the consumption of oil as CARCEL'S or the French moderator lamp, would probably command an extensive sale.—*Richardson and Ronalds.*

Detection of Sulphide of Hydrogen, Bisulphide of Carbon, and Atmospheric Air in Coal-Gas.—A quick approximative method of estimating the above in coal-gas, which has long been considered a great desideratum by chemists, has been given by THORNTON J. HERAPATH. The reagents and apparatus required are:—

1. A weak aqueous solution of caustic potassa.
2. A strong alcoholic solution of caustic potassa.

3. A solution of the nitrate or acetate of lead.

4. A standard solution of lead, containing one, two, or three one-hundredths of a grain of metallic lead, as nitrate or acetate, to one hundred or one thousand water-grain measures of solution.

5. A standard meter, such as is generally used for testing the illuminating quality of coal-gas.

6. Two Liebig's triangles, and

7. Three graduated tubes or colorimeters of uniform bore. The aqueous solution of potassa is used to absorb the sulphide of hydrogen, whilst the alcoholic is afterwards employed to dissolve the bisulphide of carbon vapor, which it converts into xanthate of potassa, a salt decomposable by heat into sulphide of potassium, sulphide of hydrogen, *et cetera*, as exhibited by the equation:—

In testing a gas by this method, one proceeds as follows:—The two triangles having been properly filled, the one with the aqueous, and the other with the alcoholic solution of caustic potassa, they are connected together by a piece of sheet caoutchouc in the usual way, and attached to the exit pipe of the standard meter, care being taken to place the one containing the aqueous solution next to the exit pipe. A known quantity, say ten, twenty, or thirty cubic feet of the gas to be examined, is then tardily transmitted through the triangles; the apparatus is slowly disconnected, and the contents of the triangles are separately poured into two different colorimeters. The solutions are next diluted with a little distilled water, mixed with a few drops of a solution of lead, and the alcoholic solution is heated to the boiling point, or until no further darkening in color ensues. The caustic alkali of both solutions is then supersaturated either with acetic or with very dilute nitric acid, and water is added to dilute to the required degree. As the sulphide of lead produced by the decomposition of the xanthate of potassa that was contained in the alcoholic solution is generally, if not always, much less in quantity than that produced by the sulphide of hydrogen absorbed by the aqueous solution of the alkali, it is advisable to dilute the former with less water. The depth of tint communicated to the fluid by the sulphide of lead in the alcoholic solution, is then compared with that produced, by adding the standard solution of lead, drop by drop, from a graduated tube, into a third colorimeter, which is filled nearly up to the same mark with distilled water, mixed with a few drops of pure citric acid, and of a solution of sulphide of hydrogen. So soon as the tints correspond, the measure of the solution in the two colorimeters is accurately adjusted by adding a little more water either to the one or the other; a little more of the standard solution of lead is then poured in, if requisite, to the trial colorimeter, and the number of measures of the standard solution that has been taken is carefully noted. The operation is then repeated with

the contents of the other colorimeter, containing sulphide of lead from the aqueous solution of potassa; and the number of measures of the standard solution of lead taken, is again read off. By a simple calculation are estimated the relative proportions of bisulphide of carbon and sulphide of hydrogen, by weight, contained in the gas examined.

For example, let *a* represent the quantity by weight of bisulphide of carbon which is equivalent to the lead contained in one thousand grain measures of the standard plumbous liquid; *b* the quantity of sulphide of hydrogen equivalent to the lead contained in the same bulk of the standard solution taken, as before explained, to produce a tint equal in intensity to that of the sulphide of lead in the alcoholic solution; and *d* the number of measures of the same solution by the aqueous solution:—then the proportion by weight of sulphide of carbon and sulphide of hydrogen contained in the number of cubic feet of gas operated upon, is obtained in the following equations:—

$$\text{Bisulphide of carbon,} \dots\dots\dots = \frac{c+a}{1000} + 2 \text{—nearly.}$$

$$\text{Sulphide of hydrogen,} \dots\dots\dots = \frac{d+a}{1000}$$

And as one hundred cubic inches of bisulphide of carbon vapor, and sulphide of hydrogen, weigh respectively at 600°, and 30 inches of Bar. 81·8167 and 36·331 grains, the result of the above calculation affords the means of ascertaining the proportion of these two substances by volume.

The presence of atmospheric air in coal-gas can be readily detected, by collecting a portion of the gas over mercury, and then passing up, first a few drops of caustic potassa, and afterwards a drop or two of a solution of pyrogallie acid. If the liquid assume a blood-red hue, oxygen, indicating the presence of atmospheric air, is mixed with the gas.

It would be quite out of place in a work like this to enlarge upon the different varieties of gas-burners, as that subject relates more particularly to mechanics. Still the Editor will cursorily glance at them, and for this purpose he cannot do better than append the following remarks from the able work of Drs. RICHARDSON and RONALDS:—

The Burners.—From the leaden pipes—in the circuit of which the meter is placed, if used at all—the gas passes to the *burners*, each of which is furnished with a separate brass tap. Good tight stopcocks are much more difficult to make for so light a substance as gas, than for liquids. The burners are very similar to those used for lamps, but as neither wick nor oil level requires special consideration, the management of the gas-burners is comparatively simple. The amount of gas consumed in a given time, however, must bear a proper relation to the supply of air, that the flame may not smoke or burn with a blue flame. This is regulated partly by the tap attached to the burner, and an excess of gas is avoided by making the aperture of the burners very small, which increases the velocity of the current. The same quantity of gas issuing from a wide orifice would produce a thick, short, and dull flame, because the surface in contact with the air would be increased. No gas flame should be allowed to issue from a wide open-

ing, for the same reason that thick massive lamp-wicks are not desirable.

When the burner has a single aperture of the diameter of a bristle, a *simple jet* is produced in the form of a long, thin, conical flame. The *bat's-wing*, or flattened flame, which the gas forms when it issues from a narrow slit, instead of a round aperture, is much more appropriate. A similar and equally good flame is produced by a burner with two apertures close to each other, the channels of which are inclined inwards, so that both the currents of gas cross each other at the base. They then form a flat flame spreading out in the form of an inverted triangle, and the burner is called a *fish* or *swallow-tail*.

Simple flames of this kind are generally burnt without any chimney. When a greater quantity of light is required, a greater intensity of flame, the argand burner, Fig. 122, is generally chosen. The gas from the pipe enters the annular space, *a a*, which is closed above by the flat plate, *b*, Fig. 123. In this plate are a number of fine apertures, arranged in a circle, and so near to each other that the separate flames unite to form a hollow cone. The gallery, *c*, supports the chimney, *d*; and to produce an internal current of air, *e*, is open at the sides. The distance between the apertures in these burners varies with the quality of the gas, as does the size of the aperture itself. An aperture $\frac{1}{32}$ of an inch is often used for coal-gas, and one of $\frac{1}{60}$ of an inch for oil-gas; for the former they should be $\frac{1}{8}$ th of an inch, for the latter $\frac{1}{4}$ th of an inch apart. These dimensions are, therefore, larger for coal-gas than for oil-gas, the latter possessing double the illuminating power of the former. The holes should be as uniformly and accurately bored as possible; if this is not done, there will be parts of the flame which will smoke. Sometimes the heat of the flame is applied to warm the current of gas before it issues from the burner, by which means the flame is less cooled, and whiter light is produced. For this purpose, the gas-pipe is formed into several revolutions at a certain height above the flame.

An important improvement upon ARGAND's burner for illuminating public places, bridges, *et cetera*, where one large lamp, and a very intense light, is preferred to a number of small ones, is the *bude burner*, proposed by GURNEY, upon the principle of FRESNEL's lamp. Two, three, or more hollow ring tubes, each furnished at the top with a circle of holes, form the principal part of the burner, and are connected at bottom with parts of the gas-pipe bent horizontally, from which they receive the gas. Each inner ring is placed somewhat higher than the one before it, so that a number of concentric flames are produced, the light of which is thrown by reflectors in the proper direction. The bude burner must not be confounded with the *bude light* of the same inventor, which is produced by conveying oxygen into the inner space of an argand oil-lamp. A similar effect

to that of the bude burner, is produced by a number of single flat flames arranged in a ring. The Victoria Bridge at Manchester, for instance, is lighted by such a burner, consisting of two concentric rings, each containing twelve, therefore altogether containing twenty-four flat flames; the inner ring, four inches in diameter, stands one inch higher than the outer, which is six and a half inches in diameter, the whole thus being rounded off in the shape of a rose. A great variety of gas-burners have been successively brought into public notice, all of which lay claim to the production of an increase of light, with a smaller consumption of gas. It is impossible, however, from a mere inspection of the flame produced by these burners, without accurately measuring the amount of gas consumed by each, to arrive at any conclusion as to which form is the most economical or generally desirable. Until, as RICHARDSON and RONALDS justly remark, impartial comparative experiments have been instituted with them all, decided preference cannot be awarded to any one in particular.

Fig. 124 is a representation of WINFIELD's lucent burner, in which the Liverpool button is applied to an argand gas-burner, and the peculiar form of chimney causes an external current of air to impinge at a certain angle upon the flame, producing the same effect as the metallic cone in the solar lamp; a basket of wire-gauze is fitted into the crutch of the burner, which moderates the supply of air from below, and prevents the flickering caused by sudden draughts. By fixing the chimney to a circular collar, which screws up or down upon the triangular support, Mr. LOWE is enabled, in his improvement upon this form of burner, to alter the direction of the external current caused by the contraction of the chimney; and by converting the button into a screw, its height can also be altered, and the internal current regulated.

Fig. 125 shows a form of burner, patented by Mr. LESLIE, in which the gas is caused to flow through a

Fig. 122.

Fig. 123.

Fig. 124.

Fig. 125.

number of small copper tubes, instead of from the apertures of an argand burner. The object of this is to effect a more complete combustion of the gas, by surrounding each single jet with abundance of air as it issues from the orifice. A low form of chimney or combustion-chamber is adapted to this burner, which

diminishes the velocity of the draught. If the gas be impure, the orifices of the copper tubes become stopped up either with sulphide of copper or ammoniacal compounds, and require to be cleansed with a stiff brush. The only effectual remedy for this objection to the burner, is the use of purer gas; and this must be obtained, when not supplied in a pure state from the gas-works, by the use of a separate purifier in each house.—*Richardson and Ronalds.*

Ventilation of Gas-burners.—Serious objections stood in the way of using gas-light in private dwellings at first, in consequence of the impurities contained in the gas, the great heat produced, and the large quantity of carbonic acid evolved; and to avoid inconvenience, some system of ventilation had to be adopted; but now, owing to the general purity of the gas, and the loftiness of rooms, this is not necessary.

HOFMANN'S BURNER.—It will not be out of place here to remark, that the very extensive and daily increasing application of gas as a source of heat, suggested to HOFMANN a small contrivance which is intended to facilitate the operations of the analyst.

The ordinary argand gas-burner, which is almost universally employed for heating small vessels, such as flasks, retorts, and test-tubes, is not adapted to the purposes of the blowpipe. In operations with the latter instrument, a simple jet of gas is required, issuing from a cylindrical orifice of rather considerable dimensions, the necessary amount of gas being adjusted by the stopcock. This simplest of all gas flames serves equally well for oxidation and reduction, and exhibits the phenomena of color in the most conspicuous manner.

The ordinary method of analysis being a combination of testing in the moist way and by the blowpipe, it is necessary either to use the two gas lamps—the one

with the argand burner, the other with the single jet—or to have a gas-stand so arranged as to admit of screwing on either the one or the other. But as it is inconvenient to multiply the number of gas lamps, especially in a laboratory in which several analytical students are working, and as unscrewing hot gas-jets is a most unpleasant operation, the above chemist endeavored to unite the two jets in one stand, dispensing, at the same time, with the necessity of taking the apparatus to pieces.

The object in view is accomplished simply by

substituting for the ordinary stopcock a three-way tap. The whole arrangement becomes at once intelligible by a glance at the woodcut, which represents the burner half size.

A is the loaded foot, into which the elbow union-

piece, B, is screwed. One end of this union is connected with a flexible pipe, not shown in the drawing; to the other screws the three-way stopcock, C. The plug, D, has only one orifice, and, when turned in a vertical direction, supplies the argand burner through the perforation, E. Into the side of the stopcock is soldered a small pipe, F, having a bore of about one-eighth of an inch. This is prolonged to the distance of one-tenth of an inch above the top of the argand burner, where it is brazed to a small support for the blowpipe, not represented in the drawing.

When the plug, D, is turned in a horizontal direction, the gas is shut off from both jets, but when turned in an inclined position, may be made to supply both jets at once, or either alternately. By this contrivance, either of the jets will be lighted before the other is extinguished.

In order that the jet may be likewise used for heating larger apparatus, there is a support, G, on which may be fixed a copper chimney, either plain or provided with the wire-gauze for producing the air flame.

ANALYSIS OF COAL-GAS.—The accurate analysis of gaseous mixtures—says Dr. FRANKLAND, in an able paper published in *Clegg's Treatise on Coal-Gas*, from which the following method is extracted—is one of the most delicate operations of modern chemistry. This arises not only from the difficulty of preserving gases, during the requisite manipulation, free from admixture with atmospheric air; but also from the circumstance, that their volume, the measurement of which is, in most cases, the only means of estimating their quantity, is liable to constant and considerable change, by fluctuations of temperature and of the pressure of the atmosphere, as well as by the dryness or humidity of the gas itself. This branch of chemical analysis owes much of its present accuracy and perfection to the admirable researches of Professor BUNSEN of Heidelberg.

All analytical operations upon gases must be conducted over mercury, which metal should be placed in a small wooden pneumatic trough, with plate-glass sides. The eudiometers, or measuring tubes, should be accurately calibrated and graduated into cubic inches and their tenths, the latter being subdivided by the eye into hundredths, when the volume of a gas is read off: such a division is readily attained by a little practice. At each determination of volume, it is necessary that the gas should either be perfectly dry, or quite saturated with moisture. The first condition is attained by placing in the gas for half an hour, a small ball of fixed chloride of calcium, attached to a platinum wire; the second, by introducing a minute drop of water into the head of the eudiometer before filling it with quicksilver. The determinations of volume must either be made when the quicksilver is at the same level inside and outside the eudiometer; or, as is more frequently done, the difference of level must be accurately measured in the subsequent reduction to a standard pressure. The height of the barometer, and the temperature of the surrounding atmosphere, must also be observed each time the volume of gas is measured, and proper corrections made for pressure, temperature, and also the tension of aqueous vapor, if the gas be moist.

Fig. 126.

The process of analysis described below has reference to purified coal-gas; the method of detecting the principal impurities being given in a former page.

1. *Estimation of Carbonic Acid.*—A few cubic inches of the gas are passed into a short eudiometer, moistened as above described; the volume is accurately noted with the proper corrections, and a bullet of caustic potassa is then passed up through the mercury into the gas, and allowed to remain for at least an hour; the volume of the gas being ascertained and deducted from the first volume, gives the amount of carbonic acid which has been absorbed by the potassa. Bullets of caustic potassa, or of any other fusible substance, should be of the size of a large pea, and may be prepared by melting the materials in a crucible, and then pouring them into a small bullet-mould, in which the curved end of a fine platinum wire has been placed. The ball attached to the wire is easily removed when cold.

2. *Estimation of Oxygen.*—LIEBIG has devised very accurate means for the estimation of this element, depending upon its rapid absorption by an alkaline solution of pyrogallic acid. To apply this menstruum, a small test-tube is filled with mercury and inverted in the trough: first, a few drops of pyrogallic acid, and then a similar quantity of *aqua potassæ*, are introduced into this tube by means of a pipette; a coke bullet—made by filling a bullet-mould containing a platinum wire with a mixture of two parts of coke and one of coal, both finely powdered, and then exposing the mould and its contents to a heat gradually increased to redness for fifteen minutes—attached to a platinum wire, is introduced into this liquid, and allowed to become saturated; it is then withdrawn, and conveyed carefully below the surface of the mercury into the eudiometer containing the residual gas of the first determination. Every trace of oxygen will be absorbed in a few minutes, and the volume being again measured, the diminution from the last reading will represent the amount of oxygen originally present in the gas. It is essential that the coke-bullet, after saturation with the alkaline solution of pyrogallic acid, should not come into contact with the air before its introduction into the gas.

3. *Estimation of the Luminiferous Constituents.*—Various methods have been employed for the estimation of the so-called olefiant gas—luminiferous constituents—in coal-gas. That which has been most generally employed depends upon the property which is possessed by olefiant gas and most hydrocarbons, of combining with chlorine, which causes their condensation to the state of an oily liquid. Hydrogen and light carbide of hydrogen are both acted upon in a similar manner, when a ray, even of diffused light, is allowed to have access to the mixture; but the condensation of olefiant gas and hydrocarbons takes place in perfect darkness, and advantage is, therefore, taken of this reaction to observe the amount of condensation which takes place when the mixture is excluded from light; the volume which disappears during this action of the chlorine being regarded as indicative of the quantity of olefiant gas present in the mixture. There are many sources of error inseparably connected with this

method of operating, which render the results unworthy of the slightest confidence. The same remark will equally apply to the employment of bromine in the place of chlorine. In addition to the circumstance that these determinations must be made over water, which allows a constant diffusion of atmospheric air into the gas, and *vice versâ*, there is also formed in each case a volatile liquid, the tension of the vapor of which augments the volume of the residual gas, and this increase admits of neither calculation nor determination.

The only material by which the estimation of the luminiferous constituents can be accurately effected, is anhydrous sulphuric acid, which immediately condenses the hydrocarbons, but has no action upon the other ingredients, even when exposed to sunlight. The estimation is conducted as follows:—A coke bullet, prepared as described above, and attached to a platinum wire, being rendered thoroughly dry by gently heating it for a few minutes, is quickly immersed in a *saturated solution of anhydrous sulphuric acid*, and allowed to remain for one minute; it is then withdrawn, leaving as little acid adhering to it as possible, quickly plunged beneath the mercury in the trough, and introduced into the same portion of dry gas from which the carbonic acid and oxygen have been withdrawn. Here it is allowed to rest for about two hours, in order to insure the complete absorption of every trace of carbide of hydrogen. The residual volume of the gas cannot, however, yet be determined, owing to the presence of some sulphurous acid derived from the decomposition of a portion of the sulphuric acid. This is absorbed in a few minutes by the introduction of a moist ball of binoxide of manganese, which may be readily made by converting the finely-powdered binoxide into a stiff paste with water, rolling it into a globular shape, and then inserting a bent platinum wire in such a manner as to prevent its being readily withdrawn; the ball being gradually dried, it will become hard, and possess considerable cohesion, even after being moistened with water, previous to its introduction into the gas. After half an hour the manganese bullet may be withdrawn, and replaced by one of caustic potassa, to remove the aqueous vapor introduced with the previous one; in half an hour this bullet can be removed, and the volume of the gas at once noted. The difference between this and the previous reading gives the volume of the luminiferous constituents of the gas. This method is very accurate; according to its author, Dr. FRANKLAND, the per centage of luminiferous constituents seldom varies, in two analyses of the same gas, more than .01 or .02.

4. *Estimation of the Non-luminous Constituents.*—These are, light carbide of hydrogen, hydrogen, carbonic oxide, and nitrogen. Their per centages are ascertained in a graduated eudiometer, about two feet in length, and three-fourths of an inch internal diameter, the thickness of the glass being not more than one-tenth of an inch. This eudiometer is furnished, at its closed end, with two platinum wires fused into the glass, for the transmission of the electric spark. A drop of water, about the size of a pin's head, is introduced into the upper part of the eudiometer before it is filled with quicksilver, and inverted in the mercurial trough; this

small quantity of water serves to saturate with aqueous vapor the gases subsequently introduced. About a cubic inch of the residual gas from the last determination is passed into the eudiometer, and its volume accurately read off; about four cubic inches of pure oxygen are now introduced, and the volume—moist—again noted. The oxygen is best prepared at the moment when it is wanted, by heating, over a spirit or gas flame, a little chlorate of potassa in a very small glass retort, allowing sufficient time for every trace of atmospheric air to be expelled from the retort before passing the gas into the eudiometer. The open end of the latter must now be pressed firmly upon a thick piece of caoutchouc placed at the bottom of the trough, and an electric spark passed through the mixture. If the above proportions have been observed, the explosion will be but slight, which is essential if nitrogen be in the mixture, as this element will otherwise be partially converted into nitric acid, the results being thus vitiated. By using a large excess of oxygen, all danger of the bursting of the eudiometer by the force of the explosion is also avoided. The volume after explosion being again determined, a bullet of caustic potassa is introduced into the gas, and allowed to remain so long as any diminution of volume takes place. This bullet absorbs the carbonic acid produced by the combustion of the light carbide of hydrogen and carbonic oxide, and also renders the residual gas perfectly dry; the volume noted after this absorption, when deducted from the previous one, gives the volume of carbonic acid generated by the combustion of the gas.

The residual gas now contains only nitrogen, and the excess of oxygen employed.

The former is determined by first ascertaining the amount of oxygen present, and then deducting that number from the volume of both gases; for this purpose, a quantity of dry hydrogen, at least three times as great as the residual gas, is introduced, and the bulk of the mixture determined; the explosion is then made as before, and the volume—moist—again recorded. One-third of the contraction caused by this combination represents the amount of oxygen, and the remainder, when this is deducted from the volume of residual gas, after absorption of carbonic acid, shows the quantity of nitrogen.

The behavior of the other three non-luminous gases on explosion with oxygen, enables the operator readily to find their respective amounts by three simple equations, founded upon the quantity of oxygen consumed, and the amount of carbonic acid generated by the three gases in question. Hydrogen consumes half its volume of oxygen, and generates *no* carbonic acid; light carbide of hydrogen unites with twice its volume of oxygen, and generates *its own volume* of carbonic acid; whilst carbonic oxide combines with half its volume of oxygen, causing the formation of *its own volume* of carbonic acid.

If, therefore, the volume of the mixed gases be represented by A; the amount of oxygen taken up, by B; and the quantity of the mixed gases generated, by C; and further, the volumes of hydrogen, light carbide of hydrogen, and carbonic oxide respectively, by x , y , and z , the following equations arise:—

$$\begin{array}{rcl} x + y + z & = & A \\ \frac{1}{2}x + 2y + \frac{1}{2}z & = & B \\ y + z & = & C \end{array}$$

From which the annexed values for x , y , and z are derived:—

$$\begin{aligned} x &= A - C \\ y &= \frac{2B - A}{3} \\ z &= C - \left(\frac{2B - A}{3} \right) \end{aligned}$$

5. *Estimation of the Value of the Luminous Constituents.*—The methods above given will show the respective quantities of all the constituents in any specimen of coal-gas; but analytical results afford no clue to its illuminating power; they give, it is true, the amount of illuminating hydrocarbons contained in a given volume of the gas, but it is evident, from what has already been said respecting the luminiferous powers of these hydrocarbons, that the greater the amount of carbon contained in a given volume, the greater will be the quantity of light produced on their combustion; and, therefore, as the number of volumes of carbon vapor contained in one volume of the mixed constituents, condensable by anhydrous sulphuric acid, has been found to vary from 2.54 to 4.36 volumes, it is clear that this amount of carbon vapor must be accurately determined for each specimen of gas, if it be desirable to ascertain the value of that gas as an illuminating agent. Fortunately, this is easily effected, for if the amount of carbonic acid generated by one hundred volumes of the gas in its original condition be ascertained, knowing from the preceding analytical processes the percentage of illuminating hydrocarbons, and also the amount of carbonic acid generated by the non-luminous gases, the operator has all the data for calculating the illuminating value of the gas. For this purpose a known volume—about a cubic inch—of the original gas is introduced into the explosion eudiometer, mixed with about five times its bulk of oxygen, the electric spark passed, and the amount of carbonic acid generated by the explosion ascertained, as before directed. If the percentage of hydrocarbons absorbed by anhydrous sulphuric acid be denoted by A; the volume of carbonic acid generated by one hundred volumes of the original gas, by B; the carbonic acid formed by the combustion of the non-luminous constituents remaining after the absorption of hydrocarbons from the above quantity of original gas, by C; and the volume of carbonic acid generated by the combustion of the luminiferous compounds—hydrocarbons—by x , one has the following equation:—

$$x = C - B;$$

and, therefore, the amount of carbonic acid generated by one volume of the hydrocarbons is represented by

$$\frac{C - B}{A}.$$

But, as one volume of carbon vapor gives rise to a similar quantity of carbonic acid, this formula also expresses the amount of the former in one volume of the illuminating constituents. For the purpose of comparison, however, it is more convenient to represent

the value of these hydrocarbons in their equivalent volume of olefant gas, one volume of which contains two volumes of carbon vapor; for this purpose the last expression need only be changed to

$$\frac{C - B}{2 A}$$

Thus, if a sample of gas contain ten per cent. of hydrocarbons, of which one volume contains three of carbon vapor, the quantity of olefant gas to which this ten per cent. is equivalent will be fifteen.

The application of this method furnishes an exact chemical standard of comparison for the illuminating value of all descriptions of gas; and by a comparison of the arbitrary numbers thus obtained, with the practical results yielded by the same gases when tested by the photometer, much valuable and useful information is gained.

Estimation of the Specific Gravity of Gas.—Although the mere determination of the specific gravity of gases is of very little use as a test of their commercial value—unless the gas is to be used for aeronautic purposes—yet, as it is still much employed by gas engineers, and as such an estimation is occasionally useful for controlling the results of chemical analysis, a method by which such a determination may be made is here subjoined.

The specific gravity of gases should be taken in a room where there is no fire, and where the temperature is liable to little variation during the time occupied in the operations. The following apparatus is necessary: First, a thin glass globe, capable of holding at least two hundred cubic inches, and furnished with a brass cap and stopcock, so accurately fitted as to prevent all ingress of air when the globe is exhausted; secondly, a small exhausting syringe or air-pump, to which the globe can be screwed air-tight; thirdly, a balance capable of weighing to one-fiftieth of a grain, when loaded with a quarter of a pound in each pan; fourthly, a glass tube, eighteen inches long, and half an inch in diameter, filled with fragments of fused chloride of calcium, and closed at each end with a perforated cork, through which passes a glass tube, of such dimensions as to admit of adaptation by means of caoutchouc tubing at one end, to the exit pipe of a small gas-holder, and at the other, to the stopcock of the glass globe.

The process consists in ascertaining the weight of equal volumes of atmospheric air, and of the gas under examination, at the same temperature and pressure. This is accomplished by first exhausting the globe by means of the syringe or air-pump, and then accurately ascertaining its weight, care being taken to allow time for the globe to assume the same temperature as that of the air surrounding the balance. The globe should then be connected with one extremity of the chloride of calcium tube, by means of a piece of vulcanized caoutchouc tube, and the stopcock being then very slightly opened, the air passing through the chloride of calcium, and thus being thoroughly deprived of moisture, should be allowed slowly to fill the globe. The latter being detached from the desiccating tube, is replaced in the balance, where it should remain undisturbed for at least

five minutes, when the stopcock is opened for a moment to equalize the pressure within and without, and the weight then accurately determined. The difference between the two determinations gives the weight of the air enclosed in the globe. The exsiccating tube should now be attached to the exit pipe of the gas-holder, and a stream of gas allowed to rush through it, until every trace of air has been expelled from the interstices of the chloride of calcium; the globe, again exhausted, is then to be attached to the other extremity of this tube, and the stopcock being slightly opened, as before, the gas, perfectly dried in traversing the fragments of chloride of calcium, is permitted slowly to fill the globe, which should, whilst still attached to the drying tube, be allowed to stand undisturbed for a few minutes near the balance, before the stopcock is finally closed and detached from the drying tube. The weight of the globe thus filled with gas is ascertained, and that of the exhausted globe being subtracted from it, the difference indicates the weight of the gas. The weight of equal volumes of gas and atmospheric air at the same temperature and pressure having now been ascertained, it only remains to divide the former by the latter to know the specific gravity of the gas. Thus, suppose the weight of the exhausted globe to be 2000 grains; that of the globe filled with dry air 2060, and with exsiccated gas 2040 grains; the weight of the volume of air equal to the contents of the globe would be sixty, and that of the same volume of gas forty grains; hence, $40 \div 60 = .6666$, the specific gravity of gas, air being taken as unity.

Unless a number of specific gravities are determined at the same time, it is indispensably necessary to ascertain the weight of the air contained in the globe previous to each determination. Care should be taken that the temperature of the room in which the balance is placed does not vary more than about one degree between the several weighings of the globe, as otherwise a considerable error will be introduced into the experiments. The globe should also be protected, as much as possible, from the heat radiating from the body of the operator during the several weighings.—*Clegg.*

Much time and space might be occupied in discussing the merits of the several apparatus to be employed in the analysis of gases, but this seems to the Editor to be quite unnecessary. The best plan will be to place before the reader the improved apparatus of FRANKLAND and WARD, which resembles that of REGNAULT and REISET in mechanical arrangement, although it differs entirely in the mode adopted for the measurement of the gaseous volumes.

The instrument, which is represented by the accompanying figure, consists of the tripod, A, furnished with the usual levelling screws, and carrying the vertical pillar, B B, to which is attached, on the one side, the movable gutta-percha mercury trough, C, with its rack and pinion, *a a*, and on the other the glass cylinder, D D, with its contents. This cylinder is thirty-six inches long, and four inches internal diameter; its lower extremity is firmly cemented into an iron collar, *c*, the under surface of which can be screwed perfectly watertight upon the bracket plate, *d*, by the interposition of

a vulcanized caoutchouc ring. The circular iron plate, *d*, is perforated with three apertures, into which the caps, *eee*, are screwed, and which communicate below the plate with the T-piece, *E E*. This latter is furnished with a double-way cock, *f*, and a single-way cock, *g*, by means of which the tubes cemented into the sockets, *eee*, can be made to communicate with each other, or with the exit-pipe, *h*, at pleasure.

F G H are three glass tubes, which are firmly cemented into the caps, *eee*. *F* and *H*, which are only slightly shorter than the glass cylinder, are each from 15^{mm} to 20^{mm} internal diameter, and are selected of as nearly the same bore as possible, to avoid a difference of capillary action. The tube, *G*, is somewhat wider, and

Fig. 127.

may be continued to any convenient height above the cylinder. *H* is accurately graduated with a millimetre scale, and is furnished at top with a small funnel, *i*, into the neck of which a glass stopper, about 2^{mm} in diameter, is carefully ground. The tube, *F*, terminates at its upper extremity in the capillary tube, *k*, which is carefully cemented into the small steel stopcock, *l*. *F* has also fused into it at *m* two platinum wires for the passage of the electric spark. After this tube has been firmly cemented into the cap, *e*, its internal volume is accurately divided into ten perfectly equal parts, which is effected without difficulty by first filling it with mercury from the supply-tube, *G*, up to its junction with the capillary attachment, and then allowing the mercury to run off through the nozzle, *h*, until the highest point of its convex surface stands at the division ten, previously made so as exactly to coincide with the zero of the millimetre scale on *H*; the weight of the mercury thus run off is carefully determined, and the tube is again filled

as before, and divided into ten equal parts, by allowing the mercury to run off in successive tenths of the entire weight, and marking the height of the convexity after each abstraction of metal. By using the proper precautions with regard to temperature, *et cetera*, an exceedingly accurate calibration can in this way be accomplished.

The absorption tube, *I*, is supported by the clamp, *n*, and connected with the capillary tube, *k*, by the stopcock and junction-piece, *l'p*.

When the instrument is thus far complete, it is requisite to ascertain the height of each of the nine upper divisions on the tube above the lowest or tenth division. This is very accurately effected in a few minutes, by carefully levelling the instrument, filling the tube, *G*, with mercury, opening the cock, *l*, and the stoppered funnel, *i*, and placing the cock, *f*, in such a position as to cause the tubes, *F H*, to communicate with the supply-tube, *G*. On now slightly turning the cock, *g*, the mercury will slowly rise in each of the tubes, *F* and *H*; when its convex surface exactly coincides with the ninth division on *F*, the influx of metal is stopped, and its height in *H* accurately observed; as the tenth division on *F* corresponds with the zero of the scale upon *H*, it is obvious that the number thus read off is the height of the ninth division above that zero point. A similar observation for each of the other divisions upon *F* completes the instrument.

Before using the apparatus, the large cylinder, *DD*, is filled with water, and the internal walls of the tubes, *F* and *H*, are, once for all, moistened with distilled water, by the introduction of a few drops into each, through the stopcock, *l*, and the stoppered funnel, *i*. The three tubes being then placed in communication with each other, mercury is poured into *G*, until it rises into the cup, *z*, the stopper of which is then firmly closed. When the mercury begins to flow from *l*, that cock is also shut. The tubes *F* and *H* are now apparently filled with mercury, but a minute and imperceptible film of air still exists between the metal and glass; this is effectually got rid of by connecting *F* and *H* with the exit-tube, *h*, and permitting the mercury to flow out until a vacuum of several inches in length has been produced in both tubes. On allowing the instrument to remain thus for an hour, the whole of the film of air above-mentioned will diffuse itself into the vacuum, and will become visible as a minute bubble in each tube, on allowing the vacuum to be filled up from the supply-tube, *G*. These bubbles are, of course, easily expelled, on momentarily opening the cock, *l*, and stopper, *i*, whilst *G* is full of mercury. The absorption-tube, *I*, being then filled with quicksilver, and attached to *l* by the screw clamp, the instrument is ready for use.

In localities where a constant supply of water from street mains can be had, the temperature of the water in the cylinder, *DD*, can be maintained perfectly constant by allowing a continuous stream, direct from the main, to flow into the bottom of the cylinder, and make its exit near the top. By this arrangement it has been proved, in an extensive series of experiments, that the temperature of a cylinder supplied from the Manchester high-pressure mains varies so very little in twelve hours, that it scarcely requires correction in the most delicate experiments,

while those which are movable are open at the top, so that the gas can be made to pass alternately up and down the several chambers, *over* the *loose*, and *under* the *fixed* diaphragms. Open covers to the compartments are indicated at D, and are closed by lids or

Fig. 130.

plates, E. To one end of the apparatus is attached a D-shaped flanged pipe, F, into which the pipes leading from the retorts are fixed, either vertically by the pipe I, or horizontally by the mouth-piece G, as may be required. The outlet pipe of the apparatus, by the hydraulic main, and thence to the gas-holder, is seen at H. K K are flues, by means of which heat is applied, and L L designates the brickwork in which the whole apparatus is set.

On the gas passing through the heated prepared charcoal, it is freed from a large amount of foreign compounds, partly by chemical, partly by mechanical action, and deposits a residuum, which possesses the properties of, and may be used as, a pigment. The gas thus purified has a much greater illuminating power than that submitted to the ordinary process of depuration.

The claim of the patentee is—1. For the separation of the impurities from coal-gas, by passing it through charcoal saturated with lime-water, and heated as described; and, 2. For the formation of a residuum, or deposit, derived from the gas, which may be used as a pigment, or color.

For the removal of the ammonia and the sulphide of hydrogen by one and the same process, a new method of purification has been adopted, and is one well worthy of confidence. The screens of the purifiers are covered with a mixture of carbonate of lime and sulphate of iron, which, subsequently exposed to the air, become carbonate of iron and sulphate of lime; and by the absorption of oxygen, the carbonate of iron leaves its carbon, and becomes partly sesquioxide of iron. The gas, streaming through this mixture—sesquioxide of iron and sulphate of lime—gives up its sulphide of hydrogen to the oxide of iron, forming sulphide of iron and water, while the carbonate of ammonia—contained also in the impure gas—decomposing the lime-salt, forms sulphate of ammonia and carbonate of lime.

When the purification is completed, and the mixture has done its work, it is exposed to the air, and the sulphide of iron absorbing oxygen, is converted into a basic sulphate of iron. Hence, the same mixture as at first is obtained, namely, carbonate of iron and sulphate of lime, with the addition of sulphate of ammonia, which may be washed out and preserved, while the

residue is employed over and over again. By this elegant process, the noxious sulphur compounds are utilized in the fabrication of sulphate of ammonia, and the mixture seems never weary of performing its duty; hence, not only is the februation performed at one process, but the noxious ingredients are converted into compounds of much value.

Another method of removing ammonia may be noticed: it consists in spreading on the screens superphosphate of lime, consisting of bones decomposed by sulphuric acid; the addition of ammonia to this, makes it a powerful and excellent manure.—*Clegg.*

CHISHOLM'S METHOD.—CHISHOLM'S method for the purification of gas consists in combining or mixing together the peculiar red earthy or ochry-looking substances found mingled with peat and the subsoil of peat, with hydrate of lime, or the mixed hydrates of lime and magnesia obtained from magnesian limestones, and their combination or mixture. He then introduces into the vessel, known to gas-makers as the dry-gas purifier, this mixture, and the foul gas passes through it until it is rendered pure; such purity being ascertained by the application of the tests usually employed by makers of gas for that purpose. The red earthy or ochry substance above alluded to, is composed chiefly of the oxides and salts of iron and manganese, and it is principally to these metallic matters that the purifying agency of the compounds is due; therefore, the greater the quantity of these oxides this earthy matter contains, the better is it adapted to the purpose for which the patentee uses it; and although the exact proportion of lime to be added is not material, yet the greater the amount of metallic matters there may be contained in the red or ochry earthy matters aforesaid, the more lime, or lime and magnesia, must be used; for every three parts by weight of metallic matters in this earthy matter, one part of lime by weight is preferred. Instead of the above red earthy matter, there are sometimes employed in the same way and proportion, the fine red sandy gravel so general around London in the neighborhood of chalk beds, or the red clay which is so common around Rugeley and other districts, or the phosphate or subphosphate of iron, known by these names to all geologists, and common in many boggy districts. All these, or any of them, he uses precisely in the way or combination described with respect to red earthy peat matters already alluded to; and he adds, that when these substances or mixtures, or any of them, have ceased to purify the gas from sulphide of hydrogen and other impurities, their powers may be again in part or altogether renewed or restored by passing or forcing through them a current of air, or by merely exposing them to the atmosphere, after which they may be used over and over again, or many times in succession.

POOLE'S PATENT.—POOLE took out a patent for improvements in regulating the flow and pressure of gas and other fluids. He remarks, that it is often desirable to deliver aeriform fluids at a certain uniform pressure, and various means have before been resorted to for effecting this object; accordingly his invention consists of combining the use of two or more governors or regulators, which, acting independently and in succession, are alleged to accomplish the desired object more completely

than has been done heretofore. The description of governors or regulators which are preferred for this purpose, are those where inverted vessels are used, working in quicksilver or other fluid, and connected to the induction valves. Supposing the apparatus to be arranged for regulating the supply of gas or other aeriform fluid, the main or supply pipe, where the regulation is to take place, is arranged to communicate in succession with two or more chambers, each having a governor or regulator, and so that no gas can pass from the main or supply-pipe to the furthestmost chamber, without having passed through, and been regulated more or less perfectly by, the previous regulators or governors; by which means the gas, supposing it to come up to the first governor or regulator at a pressure exceeding that at which it is desired to deliver it at, will act on the governor, and tends to close the valve, and thereby restrict the passage of the gas into the first chamber; the gas then passes from the first chamber or governor into the second, and, if it be still at an excessive pressure, it will be again retarded in its passage, and so on, according to the number of governors or regulators combined and caused to act in succession.

Fig. 131 shows a vertical section of an apparatus combined according to this patent, having two regulators or governors acting in succession; but other apparatus may be made with more than two, to act in succession in a similar manner. The form of regulator or governor preferred, is that where an inverted vessel is employed fixed to the valve, the action of which is to be regulated; but the form of the parts may be

Fig. 131.

varied, so long as two or more regulators or governors are combined to act in succession. No claim, however, is made to the governors or regulators separately, when two or more are not combined to act on and regulate the same supply. A is the inlet for the gas or aeriform fluid; B is a chamber, the opening, C C, out of which is capable of being more or less closed by the valve, O, which is on the stem, F, to which the inverted vessel D is fixed, the edges of which dip into mercury or other suitable fluid at E E; there being weights, G G, on the vessel D, according to the degree of pressure it is desired to regulate or bring the supply of gas or other aeriform fluid to, when it passes away at the outlet, K. The gas or other aeriform fluid coming into the chamber, B—above the desired pressure—will, to some extent, be regulated by its acting on the first regulator by raising the vessel, D, which will also raise the valve, O, in the compartment, B,

towards the opening, C C, till the quantity of the gas allowed to pass into the chamber, H, of the apparatus will be brought to nearly the desired pressure. The gas or aeriform fluid in the chamber, H, passes through the opening, J J, into the compartment, K, and acts on the inverted vessel, L, which is affixed to the stem, N, by which the valve, O, in the chamber, H, will be more or less closed, according as the pressure of the gas or aeriform fluid in the chamber, H, is more or less in excess of the pressure at which it is desired the gas or aeriform fluid should go off at the outlet, K. It would be well to state, that usually the same amount of pressure or weight, N N, is applied to the inverted vessel L, as there is by the weights, G G, to the vessel D, such being believed to be the best mode of working when using such apparatus. The vessel L, like the vessel D, dips into mercury or other liquid at its lower edges. By using a succession of regulators or governors, any want of correctness of the regulation of the first will be compensated for by the succeeding ones.

MICHAEL'S PATENT.—GEORGE MICHAEL, who has also taken out a patent for improvement in the manufacture of gas, remarks in his specification, that in the present state of progress in the different arts which co-operate together in the construction of gas-works, he thinks the power of the manufacturer may be increased, and the gas produced more economically than by the present mode, without employing large numbers of fine strong men to destroy their health, by charging red-hot retorts, through very narrow apertures, with small quantities of coal, and to perspire during twelve hours in front of an intolerably hot radiating surface. He proposes to substitute for the sinews of these men the action of steam-power; and, with this intention, he amplifies considerably the usual dimensions of a retort, in order to obtain in one distilling apparatus as much, if not more, heated surface as is now to be found in a whole bed of sixteen retorts twenty feet long; this he does for the purpose of having the floors of huge retorts all upon one and the same level, in order that the same steam apparatus used for charging and drawing one of them may perform the same operation for the others, by simply moving such apparatus upon rails in front of the retorts.

The dimensions in the clear which he prefers giving to these huge retorts are thirty feet in length, two feet in height, and about nine feet in width, the top being parallel to the floor, so that the transverse section of the interior of the retorts represents an elongated rectangular figure. These retorts are built with fire-bricks; but he observes, that if he only cemented the bricks together with fire-clay, as is usually done, the working of the retort would depend on the regular action of the exhaustor—that is to say, that should the exhaustor cease to work, the gas would pass through the joints of the bricks, an occurrence which would place a gas-work in jeopardy. To meet this great difficulty, the bricks of which the retort is made are laid in a vitreous cement, which, when subjected to the heat necessary for making gas from coal, forms a glaze, and renders the retort impermeable to gas. The best way to prepare this compound is, to pound and carefully mix together a double, treble, or a more compound fusible

silicate, in which silica, lime, potassa, soda, magnesia, oxide of iron, oxide of manganese, or bichlorate of soda, may be usefully employed; but should local circumstances not admit of this, the good effect produced by potassa, soda, or better, bichlorate of soda, in the composition of the cement intended to become vitrified, must not be lost sight of. It is evident that this cement must be formed into a paste with a small quantity of water, so as to be easily used by the bricklayer.

It will be obvious to all practically acquainted with the manufacture of porcelain, earthenware, or glass, that the idea of setting the bricks of the retorts in a vitreous cement can be carried out in an infinity of different ways, according to localities, giving in each place the preference to the cheapest of the articles here above noticed. For instance, in London, and in many other towns, recourse can at once be had to a compound silicate, which is a refuse from the glass paper manufactories—namely, the glass dust—to which an addition of two per cent. or more of manganese, and four per cent. or more of borax, can be made to facilitate the fusion of the aforesaid glass dust. In other places it may be cheaper to employ potassa or soda as a cement between the bricks, the silica and alumina of the fire-bricks, when heated, combining with the alkali and forming a vitreous glazing cement, and so on in a variety of other ways.

MICHAEL'S huge retort is furnished at each end with a cast-iron mouth-piece plate, contrived for receiving a luted lid, which is firmly secured by cotters. This retort is provided with two or more orifices at the top, by which the charge of coal is introduced by tilting waggons running on proper railways; the coal so introduced into the retort is then spread equally over the bottom by the aid of a rake, which forms the head of a rack worked by a steam-engine. The charge of coal preferred to work off in such a large retort is six tons, forming a layer of ten inches deep. When the charge is worked off, the mouth-pieces are to be opened by unfastening and hoisting the lids, and the charge of coke is pushed out in one cake by the assistance of the steam-rack, the head or rake of which being for this purpose turned upside down, so as to act with its head and not with its teeth. Such coke, if it be desired, may be received in an oven capable of being closed, and there treated with this intention by the admission of air and an injection of steam, leaving one opening for abducting the products. One great peculiarity in the construction of these huge retorts is, that they are well isolated from contact with any of those parts of the construction which are liable to cool, either by radiation or by contact with the soil; this isolation is obtained by preserving round the retorts a circumambient empty space, in which the products of the combustion in the fire-places are caused to decant their heat at different stages in their perambulation, before finally passing under the immediate foundation of the retort on their way to the main flue, which is constructed outside the foundations of the retorts, or nearly so.

The patentee then proceeds with the technical description of the construction of a retort, such as that referred to in the drawings—Figs. 132 and 133. The products of combustion, on leaving the fireplace, divide into two parts, at B and B'; one follows the course, B, C C C, till arriving at the vertical flue, D, through which it descends into the chamber, F, which is common to these, and to those products of the combustion which have followed the course, B', C' C' C', D'. During such course, the products of combustion emit part of their

Fig. 132.

heat from the orifices, E E E E, through which they ascend round the retort, so that in reality, by this phenomenon of decantation, there are formed two inverse currents on the sides of the retort, the hottest ascending, which, after having parted with a portion of its heat, will become descending; and the constant repetition of these effects will have for result the keeping of the sides and top of the retort at the same temperature as its floor or bottom. The drawings show distinctly how the under floor, the sides, and the top of the retort are constructed, for allowing this phenomenon of decantation of heat to produce its full effect everywhere round the retort. Particular stress is laid on this system of construction, which offers every possible facility to the working out of that law of nature, according to which the hotter parts of the gaseous products have a tendency to rise, and the colder to descend. It is according to the same principle that the products of combustion left in the chamber, F, are caused to descend along an inclined

Fig. 133.

plane in the six flues, G G, before entering the lower chamber, H, which delivers them through one aperture to the horizontal chimney, I. The orifice last spoken of is commanded by the damper, R, which regulates the draught of the fireplace. This damper is worked in an inclined flue, the entrance of which is to be covered by the tile, M, in front of the retort. The six inclined flues leading to the

chamber, H, are connected together sideways by the openings, J J.

The under floor of the retort is composed of three parts, differing one from another in their construction—that is to say, the floor of the retort, which is formed by bricks on edge, is separated from the fireplace by an arch of nine inches thickness, from the subsequent main flue by an arch of four inches and a half, and from all the divided flues by flat bricks two inches and a half thick, and eight inches long, laid in six parallel rows, the joints of such rows corresponding to the centre line of five rows of pillars.

Charging and Drawing of Retorts.—The interior of retort, N, receives the charge of coal through the openings, O O, which are shut by luted caps, P P, movable at will; the coal is brought to the retort-house in trucks, so arranged that when tilting their contents fall at once into a movable funnel placed for the time being in the openings, O; these dispositions are required for charging the retort quickly; and, when well adapted, as indicated in the accompanying drawings, the retort can receive its charge of six tons of coal in less than six minutes, provided that the coal be spread at the rate it falls down by proper mechanical power. The apparatus to which preference is given for producing this effect is composed of a cast-iron rake, Q, which forms the head of a rack sliding in a cast-iron frame, K K; this receives its motion from a steam-engine, S, fitted to the frame; the motion is transmitted by the ordinary mechanical contrivances. In order that the same steam apparatus may be rendered serviceable for the working of twenty-four retorts, or more, the frame here spoken of rests upon a system of wheels, T T, rolling upon rails parallel to the front of the retorts. The steam is adducted by a pipe which runs in a casement surrounded by sand or other non-conductor, the full length of the beds of retorts; this pipe is provided with small outlet branches and cocks between each two retorts, for the purpose of delivering the steam to the engine of the steam-power rake, through a movable connecting pipe. When the gas is worked off, and the charge is ready to be withdrawn, the lids of the retorts are moved, and the coke is pushed out of the retort in one lump by the action of the steam-rake, the head of which—namely, the rake—is for that purpose turned upside down by swivelling it round a collar. By this contrivance the teeth of the rake are spared, and its head, which is shaped like a strong rib, performs the work of clearing the retort. It is well to observe, that, in order to prevent the teeth or the rib of the rake wearing out the brickwork, they are kept at half an inch distance from the floor or bottom of the retort by friction rollers, suitably placed for bearing the weight of the apparatus. There are also friction rollers fitted on the sides of the rake for guiding its movement along the sides of the retort.

When the retort is at work, the gas passes off through the ascension pipe, V, and enters the hydraulic main, X, through the plunger, Y, which is suspended to a screw, and can be moved up and down for the purpose of transforming at pleasure the hydraulic main into a dry main by suppressing the dip, which contrivance is very valuable for relieving the retorts from all pressure.

Mr. ALEXANDER CROLL has taken out a patent for freeing gas from its ammonia, and a part of the sulphide of hydrogen, producing at the same time chloride of ammonium. He introduces a solution of the chloride of zinc into a vessel, upon the same construction as a wet lime purifier; on admitting the gas, double decomposition ensues; an insoluble sulphide of zinc, and a solution of chloride of ammonium, are produced. The gas must be further purified with lime in the usual way.

The specifications of a great number of other patents for alleged improvements in gas-making might be given; but as they are not of much interest, and probably of too little usefulness ever to be adopted, the Editor deems it unnecessary further to allude to them, which would only exhaust the patience of the reader with a series of dry details. In conclusion, the Editor has to express his thanks for the courtesy and information rendered to him by Mr. SAMUEL EDWARDS, formerly of the Liverpool Gas Works.

GELATIN.—*Gélatine*, French; *Gallerte*, German; *Gelatin*, Latin.—Skin, the tissue of bones, cartilages, and many analogous animal tissues, possess the well-known property of yielding to boiling water a substance capable of becoming jellied by the cooling of the menstruum. This was for a long time regarded as a peculiar organic principle, and was known by the name of *gelatin*; but, latterly, MULLER found it to consist of gelatin, properly so called, and of another particular product, which he denominated *chondrin*. It is generally assumed, though not perhaps on very sufficient grounds, as BRANDE remarks, that the gelatinous textures do not contain ready-formed gelatin, that that substance does not, in fact, pre-exist in the animal kingdom, but that it is generated by the action of hot water upon the membranous tissues.

The historical information connected with this subject is very limited. *Ichthyocolla*—the Latin synonym for *isinglass*, derived from two Greek words, signifying *the glue of fish*—is repeatedly mentioned by DIOSCORIDES and PLINY; the latter writer attributes the discovery of it to DÆDALUS.

PREPARATION.—Gelatin is obtained by subjecting fragments of hoofs, horns, hides, bones, the feet of calves, cows, sheep, *et cetera*, to the action of boiling water or steam. The resulting menstruum is skimmed and strained, so as to effect the removal of floating fatty bodies, and of any deposit which might be formed; then allowed to gelatinize by spontaneous decrease of its temperature.

It may also be procured from shavings of hartshorn, the product being tasteless, and having the advantage of being entirely free from fatty and oleaginous matters.

When gelatin is used as an article of food, the material should be of the best description, and quite fresh. Bones intended for this purpose ought to be well preserved in brine, or to be dried in a stove. Their gelatin is best extracted by the combined action of steam and a current of water percolating the fragments. Cast-iron cylinders are generally used in this part of the process. A vertical section of one of these is represented in Fig. 134, where A A A show the exterior cylinders, containing a basket or cage, B, filled with

bruised bones; *c c* the pipe conveying steam to the interior; *d*, a pipe for the introduction of water, provided with a stopcock, *E*, for regulating the quantity of the supply, and to which is accurately fitted a tube of tinsplate, *F*, closed at the inside end, and perforated on its under side with small holes, so as to allow of the percolation of the water: this tube is inserted in its proper place after the bone-cage has been introduced.

The cylinders, represented by *A A A A*, are elevated about twenty inches from the floor, and secured in their respective positions by screws; *a a* are the lids, in which are tubulures or valves; a thermometer is placed at *b*; the stopcocks, for withdrawing the gelatinous menstruum, are shown at *c c*; *d d* are small

Fig. 134.

gutters of tinsplate; *e e*, the main conduit of discharge into the cistern, *f*; *g g*, blocks and tackle for raising the bone-basket; *h*, the main steam-pipe.

When a pure jelly is required, the cylinder, after being charged with bones, is wrapped in a strong, coarse woollen material; as soon as the fatty matters cease to flow, the stopcock, *E*, which admits the cold water, is closed, as also those at the bottom of the cylinders, *c c c*, which are to be opened only at the end of every hour, but to such an extent only as to let the gelatinous solution run out, without allowing any steam to escape. The menstruum is subsequently strained, and poured into shallow vessels of tinsplate, or upon slabs of marble, slate, or compact and polished stone, to solidify. It is finally cut into shreds, *et cetera*, as may be thought proper. This is, however, only one method of manufacturing gelatin; and others, for which patents have been obtained, will be given in a subsequent part of the present article.

PROPERTIES.—When *pure*, gelatin is colorless, transparent, hard, and endued with great but variable coherence, according to the kind of tissue from which it is obtained. It is inodorous and insipid. Its specific gravity is greater than that of water. It has a neutral reaction. When heated, it softens, diffuses a peculiar odor, enters into a state of semi-fusion, bends, tumefies, and then exhales the odor of burnt horn. In the air it takes fire with difficulty, smokes, flames only some

instants, and leaves a bulky charcoal difficult to incinerate, the ashes of which consist principally of phosphate of lime. By dry distillation, gelatin gives much carbonate of ammonia, and yields in general the ordinary products of the distillation of nitrogenized substances.

In cold water it softens, intumescs, becomes opaque, but does not dissolve. A liquid which contains one-hundredth part of its weight of gelatin becomes viscous on cooling, but when it has only the one-hundred-and-fiftieth, the menstruum remains fluid. These phenomena, however, vary with the temperature. In winter the jelly is much more readily formed than in summer. If the solution of the gelatin is effected too quickly, the jelly obtained is less firm. Moreover, the result varies, not only in gelatin obtained from different tissues, but also with that obtained from the same tissue taken from animals of various ages.

It differs also according to the care which has been taken in the preparation of the gelatin; when its solution has been exposed to a temperature higher than 212°; and when it begins to sour, it loses in part the property of becoming jellied. The same happens when its solution is heated and cooled several times. If gelatin be left a long time in the open air, at a temperature of 60° to 68°, it becomes ammoniacal, and putrefies, diffusing a very fetid smell. The addition of a certain quantity of acetic acid prevents the putrefaction without destroying its adhesive power.

Gelatin is not sensibly soluble in alcohol, and when the latter is poured into its solution, lukewarm and somewhat concentrated, it coagulates in a white coherent, elastic, and slightly fibrous mass, which adheres to the vessel with much force. Like dry gelatin, it softens in cold water without dissolving in it. On evaporating the alcohol, there remains a thin transparent coating, very soluble in cold water, but which is not capable of being jellied. Common gelatin, in a dry state, treated with alcohol, gives up to it a certain quantity of fatty matter, and some substances of an extractive nature. It is perfectly insoluble in ether and in oils, both fat and volatile.

Gelatin, when in the jellied state, and treated with alcohol, undergoes a dehydration, under the influence of which it contracts much. It was by this means that GONNOR succeeded in remarkably reducing the size of a print obtained in a very hydrated film of gelatin, and transferring it, so reduced, to stone, from which he obtained a new impression, quite similar to the first, but more or less diminished.

By taking these prints, on the contrary, with gelatin very little hydrated, and afterwards steeping them in water, a dilatation of the plate is obtained, which enlarges the figures with the same regularity.

THENARD observed, that if chlorine be passed into a somewhat concentrated solution of gelatin, each bubble is surrounded with a white elastic matter, which follows it to the surface of the liquid, and which, at the moment when the bubble bursts, leaves a white glutinous matter, capable of taking a chatoyant appearance by malaxation. Only a small quantity of chlorine is required to precipitate all the gelatin, and, when this body is in excess, the deposit becomes of a light yellow, the liquor containing free

hydrochloric acid, and only a very small quantity of animal matter remaining in solution. Gelatin, combined with chlorine, is insoluble in water and alcohol; it reacts as an acid, a property of which it may be deprived by macerating and washing it with tepid water. It exhales the odor of chlorous acid, which it evolves when heated at 212° , a brownish residue remaining. MULDER states that it consists of one equivalent of gelatin $= C_{13}H_{10}O_6N_2 + Cl_2O_3$. When acted upon by ammonia, nitrogen is disengaged, chloride of ammonium formed, and unaltered gelatin separated. An opalescent, gelatinous body is simultaneously produced, the composition of which is represented by the last-mentioned chemist as three equivalents of gelatin $= 3(C_{13}H_{10}O_6N_2) + 2(Cl_2O_3)$. MULDER has also examined two additional chlorous compounds of gelatin, the first being $4(C_{13}H_{10}O_6N_2) + Cl_2O_3$; the other, $5(C_{13}H_{10}O_6N_2) + 2(Cl_2O_3)$. Much doubt exists with regard to the correctness of these results. Iodine and bromine do not give rise to any synonymous combinations.

Concentrated sulphuric acid produces a very remarkable alteration in gelatin, converting it into *sugar of gelatin*, *leucin*, *et cetera*, which will be subsequently noticed.

Nitric acid, aided by heat, transforms gelatin into oxalic acid.

Concentrated acetic acid renders softened gelatin transparent, and then dissolves it; the solution does not become viscid, but preserves its adhesive property. Diluted acids, on the other hand, do not prevent gelatin giving a coagulum on cooling.

The alkalis when dilute, and even concentrated ammonia, do not deprive it of the property of becoming jellied, but render the solution turbid by causing a precipitate of phosphate of lime. Softened gelatin dissolves at the ordinary temperature in concentrated aqua potassæ, leaving a white residuum, which is composed principally of phosphate of lime. If the solution be exactly saturated with acetic acid, and evaporated, it does not become glutinous; the gelatin, altered and combined with acetate of potassa which remains after the evaporation, is soluble in alcohol. Sulphuric acid precipitates from this menstruum sulphate of potassa, combined with modified gelatin; and if the precipitate be dissolved in water, and the liquor left to spontaneous evaporation, it crystallizes to the last drop. The aqueous solution of the salt is abundantly precipitated by the infusion of nut-gall, by chloride of mercury, and by the sesquisulphate of iron. Hydrate of lime does not alter the solution of gelatin, which dissolves much of it. The same may be said of phosphate of lime; hence the reason why so large a quantity of this salt occurs in the glue of commerce. No subsidence is occasioned in dissolved gelatin by the addition of neutral sesquisulphate of iron, until the menstruum has been boiled, when a flocculent reddish-yellow precipitate falls, consisting, according to MULDER, of three equivalents of gelatin combined with six equivalents of oxide of iron, and one of sulphuric acid. DUMAS states that gelatinous menstrea are not thrown down either by the neutral or basic acetate of lead, but, according to GMELIN, the latter causes the forma-

tion of a copious subsidence. If a gelatinous menstruum be gradually mixed with a solution of chloride of mercury—corrosive sublimate—a cloudiness is produced which quickly disappears. This effect continues till a certain quantity of the reagent has been added, when the gelatin is at once precipitated as a white, coherent, and very elastic coagulum. The behavior of gelatin with nitrate and subnitrate of mercury is synonymous. Protochloride of tin causes a brown flocculent subsidence, but the bichloride gives no reaction.

Silver and gold salts do not precipitate gelatin, but by the influence of solar light a portion of the metal is reduced. It is thrown down by sulphate of platinum in brown viscous flakes, which blacken on the filter, and are afterwards easily pulverized. E. DAVY regards this salt as an infallible test for the detection of gelatin, even in the presence of albumen, and in solutions so dilute as to be unaffected by tannic acid.

Tannic acid is a valuable and delicate test of the presence of gelatin. When added to a solution containing only one-five-thousandth part of gelatin, nebulosity is immediately apparent. When more concentrated gelatinous menstrea are treated with tincture or infusion of galls, a dense, white, caseous subsidence occurs, which, on desiccation, becomes brownish-yellow, agglutinates, and forms a hard, brittle mass, easily reduced to powder.

From the investigations of MULDER, it appears that several definite and permanent combinations of gelatin with tannic acid are capable of being formed. On commingling the pure solutions of these bodies, a neutral combination, containing one equivalent of gelatin, one of tannic acid, and two of water, is formed. According to DAVY, the compound of gelatin with oak-tannin consists of—

	Centesimally.
Gelatin,	54
Tannic acid,	46
	<hr/> 100

M. SCHIÉBEL, who obtained nearly the same results, says that one hundred parts of gelatin precipitated with a large excess of a solution of extract of oak-bark in nine parts of water, combined with 118.5 parts of tannic acid. When, on the contrary, he mixed a very dilute solution of extract of oak-bark with the solution of gelatin, without precipitating the whole of the latter, the deposit, which occupied a considerable time in subsiding, contained 59.25 per cent. of tannic acid. The gelatin was combined, in each of these cases, with different proportions of tannin, which are to each other as 1.0, 1.5, and 2.0.

Gelatin, says DUMAS, unites with various quantities of tannins derived from other sources, but never to a less extent than sixty per cent. when the precipitated menstruum contains tannin in excess.

It would sometimes be important, in researches relative to animal chemistry, to be able to separate tannin from gelatin, but this has not been effected. A dilute solution, either of caustic alkali or a carbonate, extracts much of the tannic acid, and leaves a gelatiniform, mucilaginous, swollen mass, which, with the aid of heat, dissolves in alkali like gelatin; but it is found in this case, that the solvent employed for

removing the tannic acid has also taken up a certain quantity of gelatin, and if the mass in question be digested with water, a little of the gelatin dissolves out, while the remainder is converted into that combination of gelatin and tannin which has been already mentioned as so slow in depositing.

COMPOSITION.—Ultimate analyses of gelatin have been made by numerous chemists, but with different and ill-agreeing results, the foremost among them being those of MULDER, SCHERER, and GOUDEVER: the formulæ proposed to represent its composition are, consequently, equally diverse. That, however, adopted by LÖWIG appears to approach nearer to the atomic combinations which have been examined, and to agree better with experiment than any other, and is adopted in the following tabulation:—

	Centesimally represented.				
	At. weight.	Theory.	Mulder.	Scherer.	Scherer. GoudEVER.

Sugar of gelatin, to which allusion has already been made, was discovered by M. BRACONNOT. This chemist triturated one part of pulverized gelatin with double its weight of concentrated sulphuric acid, and set the mixture aside for twenty-four hours. At the end of this time the color of the liquid was not deepened. He then added eight parts of water, and subjected the menstruum to ebullition for another twenty-four hours, keeping up the quantity of water. On diluting the fluid, saturating with carbonate of lime, filtering and evaporating, a sirup was produced, which, when allowed to remain quiescent for a month, deposited granular crystals strongly adherent to the bottom of the vessel. These were edulcorated with weak alcohol, and purified by repeated crystallization.

Sugar of gelatin possesses a marked saccharine taste, very nearly allied to that of grape sugar. It is soluble in water, but not in alcohol. An aqueous solution, if kept in admixture with yeast, exhibits no sign of fermentation. According to BOUSSINGAULT, the aqueous solution of gelatin sugar gives no precipitates with sulphate of copper, acetate of lead, or the nitrates of mercury and silver.

Nitric acid decomposes sugar of gelatin, giving rise to a peculiar compound, which BRACONNOT designated *nitrosaccharic acid*, but which it would be useless to describe here.

The composition of sugar of gelatin is as under:—

	Centesimally.		
	At. weight.	Theory.	Mulder.

Leucin, previously mentioned as being one of the products of the decomposition of gelatin by sulphuric acid, has been shown by MULDER to be formed also during the putrefaction of casein.

Leucin has a pearly lustre. It is friable, tasteless, inodorous, and greasy to the touch, and sublimes before fusion at about 340°. It is soluble in about twenty-eight parts of water at 65°, and in six hundred and fifty-eight parts of alcohol, of specific gravity 0.828, at the same temperature. A saturated alcoholic solution becomes turbid on cooling. It is insoluble in ether, and is anhydrous, and neither acid nor alkaline.

Further, leucin, as BRANDE states, is soluble without decomposition in concentrated sulphuric and hydrochloric acids. Chlorine decomposes it, forming hydrochloric acid and other products, among which is a brown resinoid substance, and a red volatile fluid. It absorbs hydrochloric acid gas, forming with it a mono-atomic combination. Its composition, as determined by MULDER, is as follows:—

	Centesimally		
	At. weight.	Theory.	Mulder.
12 Eqs. Carbon,	72	55.39	55.53
12 Eqs. Hydrogen,	12	9.23	9.22

USES.—Gelatin is employed for making jellies and blanc-manges. Considered medicinally, it is emollient and demulcent, and for this end is dissolved in water or milk, and rendered palatable by the addition of acid and sugar. Latterly, it has come into considerable use in pharmacy for the formation of capsules intended to conceal the nauseous odor and taste of medicinal preparations enclosed in them. It has likewise been used for coating pills, and certainly offers advantages not to be derived from the now almost obsolete practice of covering them with gold leaf. In the laboratory it is employed as a test for tannic acid.

PATENTS.—Numerous patents have been taken out for the manufacture of gelatin. Several of these are of importance, and will be briefly noticed.

In 1839, a patent was granted to GEORGE NELSON for improvements in the preparation of gelatin. The products of the process are of two kinds, which the patentee denominates as gelatin of the first and second quality. The best sort is opaque, and is by preference made from cuttings of the hides of beasts or of the skins of calves. The inferior variety is procured from *glue-pieces*, freed from hair, wool, and fleshy and fatty matters. The *modus operandi* is essentially the same in both cases, and is as follows:—The cuttings being well washed are macerated in caustic alkali at a temperature of 60°, until they are partially softened. Ten days is the period named as required to effect this. They are then placed in close vessels, and permitted to remain until a thorough softening—ascertained by passing a fork through them—is effected. They are now washed in a revolving cylinder, through which a current of water passes; exposed in a well-closed chamber to the action of sulphurous acid; submitted to pressure to remove the adhering water; and subjected to the action of steam at about 150°, till they are, as far as possible, dissolved. The menstruum is then strained, and set aside at a temperature of 100° to 120°, for the impurities which may have remained to subside; then

poured upon slabs of slate or marble to the depth of about half an inch, and allowed to remain there till it has sufficiently solidified, when it is cut, and washed to remove all traces of acid. It is subsequently redissolved by means of a steam-bath at the temperature of 85°, and finally re-solidified, and exsiccated by exposure to dry air upon nets.

C. R. ROPER, for whom a patent was sealed in April, 1845, prepares gelatin from bones or ivory, broken into small pieces in a digester. To each hundred-weight of material is added six gallons of water, and the vessel being closed, steam is admitted at a pressure gradually raised to thirty-two pounds per square inch for three and a half hours, when the charge is withdrawn. If the bones were in a pulverulent state, it would be requisite that the gelatin should be pressed out from the residuum; but if they were merely broken into fragments, this would not be necessary. The product is now run into shallow tins or pans to solidify, and finally placed on nets to dry in the usual manner.

The specification also includes the flavoring of the gelatin with essences of lemon or almonds, for the preparation of jellies or blanc-manges.

In 1846, ARNEY took out a patent for the preparation of gelatin in powder, and free from water, so that it is not so liable to become mouldy, while it is reduced to such a state that it readily dissolves in water upon the application of heat. Ordinary gelatin is subjected in a stove-room to a temperature which ranges from 150° to 212°, and when the moisture is entirely dissipated, it is broken to pieces, and ground, in a mill of any ordinary kind, to a fine powder. The patentee claims, secondly, the application of gelatin in a powdered state, by means of a particular method of sweetening and flavoring, from which jellies may be prepared by dissolving it in water, and blanc-manges by infusing it in milk. He also applies his powdered gelatin, when mixed with farina or starch, or starch vegetal flour, and flavored with essence of meats, culinary herbs and spices, in the way set forth in the specification, for the purpose of thickening, enriching, and flavoring soups, gravies, *et cetera*.

In 1844, Messrs. J. and G. Cox of Edinburgh patented a process, by which they obtain a perfectly pure substance, possessing a gelatinising force superior to that of isinglass.

Shoulders and cheeks of ox hides, which are preferred by the patentees, are thoroughly cleansed in water, after which they are cut into pieces by a machine similar to that used for cutting straw, and then subjected to the action of a paper-maker's pulp-mill. By this process, the gelatinous fibre is well washed and cleansed, as a stream of water flows through the mill during the whole operation, carrying off all the impurities. The material is next pressed between rollers, mixed with fresh water sufficient to effect its solution, and heated to a temperature varying from 150° to 212°. By these means a superior gelatin is speedily produced, and it is said that the gelatinising power is not weakened by a lengthened exposure to heat.

When a very pure product is desired, the grain and flesh are removed as completely as possible from the hide pieces, the albuminous matters being thus separated.

After that portion of the process already noticed has been gone through, the liquid gelatin is placed in a steam-bath, and when heated to a temperature not exceeding 160° or 170°, fresh ox blood is added, in the proportion of one gallon to seven hundred of the gelatin. As the temperature increases, the albumen of the blood becomes coagulated, partly rising as a scum to the surface of the menstruum, the other portion descending to the bottom. When the magma has all ascended, the heat is lowered, and it is removed, and the purer liquor allowed to settle for about an hour, when it is run into coolers, where it congeals, and is then cut out into any convenient way and dried, *in vacuo*, by a process similar to that for the evaporation of saccharine menstrua.

By another mode of concentration, the gelatinous solution is run upon a steam-heated surface—say pipes of half an inch diameter, placed within one-eighth of an inch apart—to the depth of about an inch. The exsiccation is then completed in the open air.

A patent was granted, in 1847, to G. P. SWINBORNE, for improvements in the manufacture of gelatin by the following process:—Hides or skins, or those parts of them known as glue-pieces, are cut into shavings, or thin slices or films, by any suitable instrument; these are then soaked in water, which is changed two or three times each day, until no smell or taste can be detected either in the water or in the shavings, which are then removed, subjected to heat with water sufficient to cover them when pressed down in any suitable vessel. The gelatin, thus dissolved, is strained, subjected to slight pressure, and run in thin films upon a smooth surface of slate or other material to *set*, and then placed on nets to dry in the ordinary way, and finally cut into shreds.

A fish gelatin is also prepared by the same method from cod sounds, which forms a good and cheap substitute for isinglass for clarifying liquids.

ISINGLASS.—*Colle de poisson*, French; *Fischleim*, German; *Ichthyocolloia*, Latin.—The repeated mention by DIOSCORIDES and PLINY of *ichthyocolloia* has already been noticed.

Isinglass is obtained from the air-bag, or sound, as it is sometimes termed, of various fishes, many of which are still unknown. The finest kinds are produced by species of the *Acipenser*, and some other genera, as the *Morrhua*, *Silurus*, and *Gadus*.

The method of preparing the air-bags for sale, differs considerably, according to the country in which it is conducted. The commercial *pipe*, *purse*, and *lump* isinglass consist of the bag desiccated, but unopened. The *leaf* and *honeycomb* kinds are examples of the bladder cut open and dried unfolded; in the *staple* and *book* varieties, it is folded, while in the *ribbon* isinglass, it is rolled out. It is *picked* or *cut* before importation into Great Britain.

DESCRIPTION.—For a delineation of the various kinds of isinglass, the Editor holds himself indebted to Dr. PEREIRA. The very able dissertation of that pharmacologist on the various fishes from which isinglass is prepared, must, however, be omitted, as out of place here.

1. RUSSIAN AND SIBERIAN ISINGLASS.—The isinglass produced in the Russian empire is principally

obtained from the sturgeons. These cartilaginous fishes constitute the genus *Acipenser*. But this is not the only genus from which isinglass is obtained in Russia, for it is also procured from the *Silurus glanis*, which Dr. ROYLE suggests may be the source of the Samovey isinglass of commerce. BRANDE thus describes the preparation of Russian isinglass:—The swimming bladder is cut open, washed, and then exposed to the air with the inner silvery membrane turned upwards. The latter is then stripped off and placed in damp cloths, or left in the outer covering, and prepared or kneaded. It is then taken out of the cloths, and either merely dried—*leaf* isinglass—and twisted in a serpentine manner, between three pegs, into the shape of a horse shoe, heart, or lyre—*long* and *short staple*—or folded in the manner bookbinders fold printed sheets of paper—*book* isinglass.

Dr. PEREIRA observes in a foot-note to the above account of BRANDE, that though it agrees with the statements given by PALLAS, GMELIN, GEORGI, and TOOKE, there must be some inaccuracy in it. The immersed membrane of the swimming bladder is insoluble, though, according to BRANDE's view, the innermost is the gelatinous membrane. According to T. W. C. MARTIN, the swimming bladders are first placed in hot water, carefully deprived of adhering blood, cut open longitudinally, and exposed to the air, with the inner delicate silvery membrane upwards. When dried, *this fine membrane is removed* by beating and rubbing, and the swimming bladder is then made into different forms.

Several kinds of leaf isinglass, says BRANDE, are imported from Russia. The finest kind is that from Astrakhan, one variety of which is said to be obtained from the Beluga—*Acipenser huso*. These are imported from St. Petersburg. The Samovey leaf is an inferior kind brought from Taganrog. Sisane leaf is the produce of a small fish, each piece measuring only about two and a half inches each way, and weighing about a drachm; it looks like pieces of dried bladder, marked by two fibrous or muscular bands. Kroski isinglass is in small circular membranous discs. Long staple isinglass is of fine quality, and is the produce of the Oural. It is usually imported loose; at times it is strung on ropes, and this latter kind is preferred. Of short staple, three varieties are known: the finest is from the Oural, and is distinguished by the name of Patriarch, but it is very scarce. The Astrakhan short staple is one of the best kinds. The Samovey short staple is of inferior quality. Two sorts of book isinglass are met with; that from the Oural is excellent, but the Samovey product is little regarded. Siberian purse isinglass is of moderately good quality, and is in general demand. A small kind on strings, in a necklace form, is sometimes imported.

2. **BRAZILIAN ISINGLASS.**—This is imported from Para and Maranham, and, according to GUIBOUT, is sometimes denominated Cayenne isinglass. The fishes which produce it are not known, but it is obvious, from a superficial examination of the commercial specimens, that they must have been obtained from at least several species or genera. YARREL suggests the genera *Pimelodus* and *Silurus* as the sources of it.

It comes over in the form of *pipe*, *lump*, and *honeycomb*.

Pipe Brazilian isinglass must have been procured from a large fish. It is prepared by drying the swimming bladder unopened, and in some cases this is found distended with air. Each air-bag or *pipe*, as it is called, is from ten to twelve inches in length, and two or two and a half inches broad, weighing about five ounces, in shape somewhat conical, tapering at one extremity, but broader at the other, where on each side is a cæcal prolongation. It is devoid of smell. Lump Brazilian isinglass consists of two swimming bladders placed side by side, considerably separated at one end, but communicating with each other at the diverse extremity. When perfect, each specimen bears some resemblance to that of a torpedo. A perfect, though not very large lump, measured eight inches in length, and at the greatest latitude, five inches. Its weight is about six and a half ounces. It consists of three portions, separated by constrictions. The largest portion is five inches broad, and three and a half inches in length, flattish in front, rounded posteriorly. It consists of two sacs, placed one on each side. The middle portion is oblong, three inches in length, and two in breadth. This is also formed of two sacs, communicating with the preceding portion. The third portion is oblong, one and a half inches long, and three-fourths of an inch wide. This consists of one sac only, into which both sacs of the middle portion open.

Honeycomb Brazilian isinglass appears to be the largest quantity of the lump variety split open. The latter is sometimes softened, and rolled out into thin ribbons, in this country. On account of its deeper color and less solubility, Brazilian isinglass is not in demand for domestic use; though, as it is sold in the cut state, it is probably largely intermixed by shopkeepers with the finer kinds of Russian isinglass, and sold as such. As it is moderately cheap and soluble, it is in extensive use for fining by brewers, who are the principal consumers of this variety. When digested with boiling water, it leaves a large proportion of undissolved white matter of a starchy consistence.

3. **New York Isinglass.**—Occasionally, ribbon isinglass is imported from New York. It is in thin strips of several feet long, and from an inch and a half to two inches in width. It is less soluble than Russian isinglass, and affords a dark-colored solution. Dr. J. V. C. SMITH states that it is obtained from the air-bladder of the common Hake—*Gadus merluccius*—which is macerated in water for a short time, and is then taken out and subjected to pressure between two iron rollers, by which it is elongated to the extent of half a yard or more. It is then carefully dried, packed, and sent to market. The common cod—*Morhua vulgaris*—yields a poorer kind of isinglass; but the hake only is known to the extensive manufacturers as fit for their purposes.

4. **Hudson's Bay Isinglass.**—Dr. PEREIRA was unable to ascertain from what fish this isinglass is procured. It comes over in the purse form. One specimen measured twelve inches in length, and three and a half in diameter; its weight is one ounce and a half. It is of a light yellow color, translucent, and free from

taste and smell. The inner lining of the sac, which may be readily stripped off, is insoluble in water; the remaining membrane dissolves in boiling water.

5. *East India Isinglass*.—It appears that, for a long period, this has been exported from Calcutta to China, but it has only recently occupied the attention of Europeans. It is probably the produce of a species of *Polynemus*. But, according to Dr. ROYLE, the fishes which Dr. BUCHANAN named *Bola*, and several species of *Silurus*, especially *S. raita*, also yield isinglass. Most of the specimens of Indian isinglass examined by Dr. PEREIRA had an unpleasant fishy odor, which rendered them totally unfit for household use, and greatly deteriorated their value for domestic purposes. A sample of East Indian purse isinglass, examined by Dr. PEREIRA, consisted of an unopened swimming bladder, flattened and dried. Its shape is oval-oblong, its length nine inches, its breadth three and a half inches, its weight seven and a half ounces. It has a strong fishy smell, and is of a dark color.

Another kind—East India leaf isinglass—is the sac merely laid open and dried. It is eight or nine inches long, six or seven inches broad, and about three-tenths of an inch thick. A third variety—East India rolled leaf isinglass—which Dr. PEREIRA received from Dr. ROYLE, appears to have been formed by rolling out the preceding kind into thin plates. One specimen was about eighteen inches long, three and a half inches wide, and one-tenth of an inch thick. Some of the sheets are covered with a thin film of chalk.

Picked East India isinglass is in small shreds, two or three inches long, and tapering at the extremities. It is hand-picked in India by the natives.

Manilla isinglass has been imported recently as *thin cake*. It is white and clean, and is equal in quality to Brazilian or Samovey book. The fish which yields it is found in the river of Manilla, and on the coasts of the Philippines, Luconia. It is smaller than the Brazilian, but greatly resembles the lump variety of that kind, and the fish is probably an allied species.

6. *Cod Sounds*.—These, in the dried state, are brought from Scotland, and used as a substitute for foreign isinglass. They are, however, usually preserved soft by salting, and dressed for the table.

Para Isinglass.—A substance has lately been imported under the name of isinglass, which, on examination, proves to be, not the air-bag, but the dried ovary of a large fish.

It consists of bunches—somewhat resembling those of grapes—of ovoid or rounded masses, attached by peduncles to a central axis; by immersion in water, the latter is found to be a convoluted membrane, to one side only of which these ovoid masses are attached. When soaked in water, the fishy odor of this so-called isinglass is very obvious. The ovoid masses are *ova*, are highly vascular on the surface, and are filled with an animal substance of a yellow color. In general appearance, they resemble the vitellus of a shark or ray.

The *Sudis gigas*, a large osseous fish, upwards of six feet in length, is found at Para. Its flesh is eaten by the lower classes in a dried and salted state, and its swimming bladder constitutes one of the kinds of

Brazilian isinglass imported into London. It is probable that the ovary of this fish constitutes the false isinglass in question. If not from this fish, it is probably obtained from some allied genus—as *Amia*—of highly organized osseous fishes.—*Pereira's Materia Medica*.

PROPERTIES AND COMPOSITION.—The properties of isinglass are nearly the same as those of gelatin.

Isinglass was first analysed by Dr. JOHN, but his results are very questionable. They are as follow:—

	Centesimally.
Gelatin,	70.0
Osmazom,	16.0
Membrane insoluble in boiling water,	2.5
Free acid, and salts of potassa and soda,	4.0
with some phosphate of lime,	7.5
Water,	100.0

It appears that the Bengal isinglass yields, on analysis, gelatin, albumen, osmazom, a trace of odorous oil, and a small amount of inorganic matter. The quantities of the first two mentioned principles contained in three several samples of isinglass were respectively:—

	Centesimally.		
	I.	II.	III.
Gelatin,	86.5	90.9	92.8
Albumen,	13.5	9.1	7.2
	100.0	100.0	100.0

USES.—The more common kinds of isinglass, especially the coarse Brazilian, are used by brewers for fining beer, and have been noticed in their application for that purpose. They are also employed for the clarification of wines, and various other liquids.

Court Plaster is formed by brushing a solution of isinglass, mingled with a little tincture of benzoin, over black sarsenet. LISTON's isinglass plaster is similarly made with oiled silk.

Isinglass also enters into the composition of those preparations known as *marine glue*, *diamond cement*, *et cetera*. The latter is made by dissolving isinglass in dilute alcohol. These ingredients are put in a bottle loosely corked, which is then placed in a vessel containing boiling water, and simmered for about an hour. When cold, it should be an opaque, milk-white, hard jelly; it is re-dissolved by immersion in warm water, the cork of the bottle having been previously loosened. The addition of a little spirit is required, after some time, to replace that lost by evaporation.

A better article than this may be obtained by soaking fine isinglass in cold water; when it has swelled out, spirit is added, and the bottle containing these set in a pan of cold water, which is gradually brought to the boiling point, when the isinglass becomes one uniform pulp, free from lumps or fibres.

These preparations have a tendency to become mouldy, which may be diminished or removed by the addition of a few drops of any essential oil.

ADULTERATION OF ISINGLASS.—The quality of cut isinglass is estimated, says Dr. REDWOOD,—1. By its color; that which is cut fine by machinery being, *ceteris paribus*, the whitest and generally most esteemed. 2. By the odor emitted after breathing upon it; that being the best which is least disagreeable in this respect. 3. By the extent of its solubility in water. 4. By the con-

sistency, transparency, and flavor of the jelly which it gives. This practical method of examination is that alone by which slight shades of variance may be discovered; yet a difference of flavor, which only a practised palate, or careful comparison with an approved specimen could detect, is often important in an article intended for the diet of the fastidious invalid, and a slight superiority in this respect will, therefore, command a much increased price.

WARINGTON and REDWOOD have shown that sheet gelatin is rolled between sheets of isinglass in the moistened state, so as to form a ribbon in which the two substances would be united.

This may be detected by means of the microscope, the separate strata being in many cases clearly discernible. The amount of inorganic matter in the product is also a clue as to whether it is or is not adulterated, since isinglass gives an ash of a *reddish color*, amounting only to a half per cent., while gelatin gives, according to REDWOOD, not less than three per cent. of *white ash*.

They may also be distinguished from one another, says Dr. REDWOOD, by means of caustic potassa. When cut isinglass is macerated in a cold solution of caustic potassa, it will speedily become transparent, and, after the lapse of a few hours, if occasionally stirred, it will be dissolved, forming a clear and colorless solution. After allowing this to stand for some time, a *very slight* flocculent precipitate will be deposited, which, in operating on twenty or thirty grains of isinglass, will be scarcely perceptible. *Cut gelatin*, by the same treatment, becomes opaque; even those specimens which were so, to a certain extent, previously, will assume increased opacity after immersion. The gelatin ultimately dissolves, as does the isinglass; but the solution is not transparent, and after some time a *copious* flocculent deposit is formed.

A sample of hand-cut isinglass, examined by WARINGTON, had a great deal of acid adhering to it, which he considered to arise either from the acid having been used for the purpose of improving an inferior isinglass, so as to render it saleable, or from its admixture with gelatin prepared by means of an acid.

GLUE.—*Colle forte*, French; *Tischlerleim*, German. —Glue is an impure desiccated gelatin, obtained from various sources. The principal substances employed are scraps of ox and other thick hides, which afford the strongest product; the debris of the tan-yards, of leather-dressers, morocco-leather manufacturers, *et cetera*. The tendons and intestines of many animals, rabbit skins deprived of their fur, scraps of parchment, old gloves, and many other apparently worse than useless matters, all contribute their quota in the manufacture of glue.

When the fresh glue-yielding substances are not to be immediately employed, it is always requisite to submit them to some antiseptic treatment till they are required for use.

This preservation often forms the base of a particular branch of industry, which has for its object to prevent the fermentation of the raw materials, and to dry them to avoid the expenses of transport. These results are obtained by simply macerating them during

fifteen to twenty days in milk of lime, which is repeatedly renewed. After taking them from the lime bath, they are spread in the open air to drain and dry. This desiccation is accelerated by turning them over with a fork several times a day. When sufficiently dried, the materials are packed up and sent to the glue factory.

The calcareous liquor serves to dissolve the blood and some soft parts; it attacks the epidermis, and predisposes the tissue to be more easily converted into gelatin. Before employing these glue-yielding materials, the manufacturer is in the habit of completing these effects by again immersing them in a weak milk of lime, which frees them still further from any soluble animal impurities. When they are much swollen and easily penetrated, they are several times rinsed in water to remove the excess of calcia. They are then spread upon hurdles, being turned occasionally to carbonate the free alkaline earth, which might subsequently be injurious to the glue. It is not necessary, however, to dry the material, as when put into the boiler it dissolves faster when in a soft or tumefied state.

Formerly the glue pieces, having been cleansed as above described, were thrown loose into the caldron, which was of copper, rather shallow in proportion to its area, and flat-bottomed. Above the true bottom there was a false one of copper or iron, perforated with numerous holes, and standing upon feet three or four inches high, the animal matters being thus upheld from contact with the fire.

Now, however, the material is placed in a wide-mouthed bag or net, made of rope, and spread open in the caldron, which contains a light framing of iron, to prevent the bag adhering to the sides or bottom. Water is then added, and gradually brought to ebullition. As the animal substances decrease in bulk, fresh additions are made, the whole being occasionally agitated or pressed down by means of poles.

The progress of the operation is readily ascertained by withdrawing a sample of the menstruum, and setting it aside for a few minutes to cool. If a clear and consistent jelly be obtained, the boiling has been carried to a sufficient extent, and the mouth of the glue-bag having been securely tied up, it is slowly raised by appropriate machinery, until it comes in contact with, or is partially coiled round, a large beam immediately above the caldron, which expels the fluid. In this state it is left to drain. The solution in the boiler will require evaporation before it is sufficiently concentrated for making glue.

The contents of the bag are subjected to ebullition for a second and a third time, and by this means afford *size*. When the resulting solutions are too dilute for either glue or size, they are employed instead of water for extracting the glue from fresh materials; the refuse in the bags, after all available matter has been extracted, is sold for manure, and every particle of animal substance is turned to account.

When sufficiently concentrated, the glue is transferred from the caldron to the *settling-back*, where such a temperature is maintained, that its fluidity is preserved. The impurities by this means subside, and should the manufacturer wish a very fine product, he

can also at this time add such fining or clarifying agents as he may prefer.

The glue is run off hence into wooden *coolers* or *boxes* about six feet in length, two in depth, and one in breadth. The apartment in which this is done ought to be as cool and dry as possible, to favor the solidification of the gelatinous menstruum, and the floor should be kept scrupulously clean, so that should any glue escape it may be recovered.

Having become a firm jelly, the glue is cut out into cubic masses, each of which is deposited in a kind of wooden box, open to the back in several slits or divisions, of a size corresponding to the thickness which the cakes of glue are required to have. It is then cut into slices by passing a brass wire stretched in a frame, like that of a bow-saw along the slits. The resulting cakes of glue are deposited upon nets, which are stretched in wooden frames, and are thus removed to the sheds, where they are placed in piles, due intervals being allowed for the circulation of the air. They are turned two or three times a day.

The drying of the glue, says Dr. URE, is the most precarious part of the manufacture. The least disturbance of the weather may injure the product during the first two or three days of its exposure. Should the temperature rise considerably, the gelatin may become soft and unshapely, so much so as to run through the meshes upon the pieces below, or to get attached to the strings, and surround them so as not to be separable without plunging the net into boiling water. If frost supervene, numerous cracks may be formed in the cakes, from the congelation of their water. Such pieces must be remelted. Even a slight fog produces, upon newly-exposed glue, a serious deterioration; the damp condensed upon its surface occasioning a general mouldiness. A thunderstorm sometimes destroys the coagulating power in the whole laminæ at once; or causes the glue to *turn* on the nets. A wind too dry or too hot may cause it to exsiccate so quickly, as to prevent it from contracting to its proper size without numerous cracks and fissures. Thus, as TOMLINSON remarks, the manufacture is subject to many vicissitudes, and can only be profitably and conveniently carried on in temperate and equable weather. The drying, however, is not entirely finished in the open air. When the glue is about three parts dry, it is removed into lofts, where, in the course of some time, the hardening is completed. But, as the surfaces of the cakes become mouldy and soiled, it is necessary to scour them with a brush and hot water, and set them up to drain. They are then finally desiccated in a stove-room at an elevated temperature, which, when they have once become solid, only serves to harden and improve them.

In France, a considerable quantity of glue is made from bones, which are digested in hydrochloric acid, for the purpose of removing the phosphate of lime.

The following is the *modus operandi*:—It is proper to observe that all bones do not answer for this manufacture. Only spongy bones can be used; the ribs, the back-bone, the lower jaw-bone of animals, and the horns, are those which yield the greatest amount of gelatin. The bones are broken as small as possible by means of an axe. Some hydrochloric acid of

36° Twaddell is mixed with a quantity of water, so as to reduce the mixture to 13°, which can be ascertained by means of the acidimeter. The crushed bones are put into a vessel, and the above-mentioned preparation poured over them so as to cover them completely. The vessel is covered close with a wooden lid, and the bones are thus left to macerate for thirty hours. When this period has elapsed, it must be seen if the bones are softened; for otherwise, if the acid was deficient in strength to extract from them the lime and alkali, in that case it would be requisite to change the vessel, and to give them a new maceration with a mixture of 9° Twaddell strength. When sufficiently prepared they are withdrawn, and thrown into a bath of weak lime-water, where they are left to steep eight days; they are then removed, washed with fresh water, and put to steep in a fresh portion of water daily for ten or twelve days, for the purpose of removing from the bones the acid which may have penetrated them—then dried. These glues or pastes are now good for the market, and sell at about fifty shillings the six hundred pounds.

This, says Dr. URE, is a poor article, possessing little cohesive force. It dissolves almost entirely in cold water, which is the best criterion of its imperfection.

PROPERTIES.—Glue is commercially judged of by its color, and freedom from cloudy or black spots when held up before the light.

The better sorts of glue are transparent, especially the thin cakes of *Salisbury glue*, which are of a clear amber color. The chemical characteristics of glue are similar, as a matter of course, to those of pure gelatin.

According to SCHATTENMANN, fresh glue dries much more readily than glue that has been once or twice melted. He states that dry glue absorbs different quantities of water in proportion to its quality, and on this property he has proposed a method of testing it.

Fresh glue contains water of composition, or water more intimately united with the glue than that which it acquires during the melting. The combined water of dry glue disappears in the course of successive meltings and solidifications.

Glue in thin laminæ is usually of better quality than that which is in thick ones, even when made from the same material, because the former admit of a more rapid desiccation than the latter.

In applying SCHATTENMANN'S test, dry glue is immersed for twenty-four hours in water at a temperature of about 60°. A jelly is thus formed, the qualities of which will fairly represent those of the glue. For example, the finest ordinary glue, or that made from white bones, absorbs, in the time specified, twelve times its weight of water, so that a plate weighing three grammes produces thirty-nine of fine elastic jelly. Glue from dark bones takes up nine times its weight of water, and a soft brown jelly is produced, devoid of elasticity and consistency, and falling to pieces when handled.

Well-dried glues are much less hydrometric than badly made ones, or those fabricated from inferior materials. The latter are liable to putrefaction.—Tomlinson.

APPLICATIONS.—The common, but important use of

glue in carpentry, cabinet-making, *et cetera*, is well known.

There was formerly a large consumption of it for the sizing of paper; but since this has been made without manual labor, it is almost wholly disused for this purpose.

The latter employs it in the preparation of his felt; and the letterpress printer, in conjunction with molasses, as a flexible and cleanly covering for his inking rollers.

At the beginning of this century, glue was introduced in Germany for making moulds for casting, but it was not employed in this country till the year 1826, when DOUGLAS FOX used it for taking casts of anatomical preparations, calcareous concretions, vegetal substances, *et cetera*. He first mixed it with treacle, for the purpose of giving to it more elasticity, but this discolored all white surfaces, and the plan was abandoned.

In 1844, FRANCHI formed a series of casts in plaster composition, in imitation of ivory; and, in 1846, the Society of Arts in London awarded to him a prize. The nature of the material was unknown at the time, but it was subsequently shown to be pure gelatin. The inventor has since employed it for modelling very intricate and ingenious devices.

STATISTICS.—A very large amount of glue, manufactured in England, is undoubtedly passed off as Russian; yet, nevertheless, a considerable quantity is imported. The returns of imports and exports, from the years 1850 to 1855, are subjoined. The reader cannot fail to notice the large decrease in the quantity imported during 1855, owing to the hostilities with Russia :—

The quantity imported is gradually lessening, owing, most probably, to the great improvements which have been effected in the British manufacture during the last few years.

GLASS.—*Verre*, French; *Glas*, German; *Vitrum*, Latin.—The discovery of glass is, without contradiction, one of the most important services which accident or chemistry has rendered to civilization. Without speaking of the economical uses of this compound, and considering it only with reference to its applications in the

study of natural phenomena, it is impossible to doubt the singular influence it has exerted on the progress of science. It is chiefly by its aid that astronomy has attained a perfection so wonderful; by it also naturalists have been enabled to study under the microscope a host of phenomena which heretofore escaped notice. But perhaps of still greater importance is the use which is made of it by chemists in their experiments. It requires no profound chemical knowledge to recognize the fact, that to glass is chiefly owing the present advanced state of the sciences, so fruitful in marvellous applications. Every one, says LIEBIG, is familiar with most of the properties of this curious substance; its transparency, hardness, destitution of color, and stability under ordinary circumstances: to these obvious qualities one may add those which especially adapt it to the service of the chemist, namely, that it is unaffected by most acids or other fluids. At certain temperatures it becomes more ductile and plastic than ware, and may be made to assume in the flame of a common lamp the form of every vessel needed in the laboratory, and of every apparatus required by experimenters.

The use of glass in our windows, remarks TOMLINSON, instead of the *louvre* boards of old, has introduced a degree of comfort into the meanest dwelling which previously did not appertain to the costliest palace. By means of this contrivance the light is filtered from the wind, the rain, and the cold; the one can be enjoyed without being inconvenienced by the other; and one can, in conjunction with the improved methods of warming, create an in-door climate, adapted to the desires and feelings of the dwellers. The employment of glass in many domestic articles of furniture contributes to cleanliness and health, for the slightest soil on glasses or decanters is revealed by this most transparent material, and the purity of the water and other liquids contained in them is physically tested by the same means. Even the mirror, adorning the rooms, reminds one of the necessary attention to personal appearance, which self-respect, as well as respect for society, demands.—*Tomlinson*.

The great Dr. JOHNSON has appositely remarked, that it might contribute to dispose one to a kinder regard for the labors of his fellow, if he were to consider from what unpromising beginnings the most useful productions of art have probably arisen. Who, when he first saw the sand or ashes, by casual intension of heat, melted into a metalline form, rugged with excrescences and clouded with impurities, would have imagined that in this shapeless lump lay concealed so many conveniences of life, as would, in time, constitute a great part of the happiness of the world? Yet, by some such fortuitous liquefaction was mankind taught to procure a body, at once in a high degree solid and transparent, which might admit the light of the sun, and exclude the violence of the wind; which might extend the sight of the philosopher to new ranges of existence, and charm him, at one time, with the unbounded extent of material creation, and at another with the endless subordination of animal life; and what is of yet more importance, might supply the decays of nature, and succour old age with subsidiary sight. Thus was the first artificer in *glass* employed, though

without his knowledge or expectation. He was facilitating and prolonging the enjoyment of light, enlarging the avenues of science, and conferring the highest and most lasting pleasures: he was enabling the student to contemplate nature, and the beauty to behold herself.

It is not a little remarkable that glass, which is applied so extensively and to so many purposes, and the varying properties of which exercise so marked an influence in its different applications, has, notwithstanding, never been the subject of a series of decisive experiments, calculated to establish the theory of its fabrication. Not that this theory has not been nearly, if not wholly elucidated; but that it is scarcely to be looked for in the works published on glass. The greater part of these were written at a period when the part which silicic acid performed was not defined or understood; and among the recent works on the subject, KNAPP'S is the only one which discusses it in a thoroughly scientific manner.

Definition.—It is stated in the *Encyclopedia Britannica*, that the general term *glass* is employed by chemists to denote all mineral substances which, on the application of heat, pass through a molten state into hard and brittle masses, and which exhibit when broken, though not always transparent, a lustrous fracture. The glass of commerce, however, to which the present article will be restricted, or the transparent and artificial substance which is usually distinguished by this name, is produced by the igneous fusion of silicious earth with certain alkaline earths or salts, or with metallic oxides.

The etymology of the word has been much disputed. It is derived by some from the Latin *glacies*, ice, its resemblance to which is thought to have suggested the title, and *glacies* may be a contraction for *gelacies* from *gelu*, frost. Others have remarked, that the common Latin designation of this substance is *vitrum*; and as the Romans applied this term, in common with the word *glastum*, to the plant which is now called woad, they have deduced it from the latter of these, either because the ashes of this plant were used in the manufacture of glass, or because it exhibited something of the bluish tinge which is procured from woad. *Glassum*, the name given to amber by the ancient Gauls and Britons, has also been assigned as the origin of the word. But none of these etymons appears very satisfactory. The most plausible theory is that which derives the term from the Saxon verb *glis-nian*, or the German *gleissen*, which are probably contractions of the Anglo-Saxon *gel-ixan*, to shine, to be bright. This view is in a great degree confirmed by the sense in which the term glass and its derivatives are employed by our older writers, who frequently apply it to shining or glittering substances, without reference to color or transparency.—*Encyclopedia Britannica*.

HISTORICAL NOTICE.—In the most remote ages the art of blowing glass into bottles, making it into vases, tinging it to imitate precious stones, melting it in huge masses to make pillars, rolling and polishing it into mirrors, and staining it in parts, were all perfectly known. As stated by some authorities, Egypt, the parent of so many collateral arts, is to be looked to as its source. According to others, its discovery origi-

nated with the Israelites, who set fire to a forest, and the heat becoming so intense as to make the nitrate of soda and sand melt and flow along the mountain side, they afterwards imitated artificially what had first been effected by accident. If PLINY is to be credited—an author, whose version of the subject has so often been reproduced with all the gravity of history—the discovery of glass was made by some Phœnician soda merchants, who, having landed on the banks of the river Belus, served themselves with blocks of soda to support the vessel in which they prepared their food, and these masses melting with the heat, transformed into glass the sand on which they rested. When one knows the temperature necessary for the making of glass, and has seen the interior of a glass furnace in operation, this story will be rejected as fabulous. Chance had doubtless its share in the invention of glass; but there might have been found among the arts known to the ancients, phenomena better fitted to awaken the attention of an observant spirit. The pottery manufacture and the extraction of metals require the employment of violent and sustained fire, which is sufficient to give rise to fusible silicates, more or less analogous to glass. That an intelligent potter might have attempted to reproduce at pleasure the vitreous tears which formed accidentally upon his products; that by dint of repeated trials he might have been led to remark the influence of ashes on the clay, and that thus he might have succeeded in producing glass, is easily conceived. However this may be, the anecdote related by PLINY ought to be ranked with those idle tales or mere conjectures by which the ancient commentators sometimes attempted to fill the gap created by the silence of history, and which were afterwards transformed into articles of faith by some mistake of a copyist, or by some blunder of a new commentator. It is a point, however, on which there can be no doubt, that glass was known to the Phœnicians, who for a long time retained the monopoly of it, favored by the union of natron, sand, and fuel, in a country situated on the shores of the sea.

There are several references to glass in the Bible. BALLANTYNE remarks that the Hebrews must have become acquainted with glass while in Egypt, and in consequence of their proximity to the Phœnicians; and it is now generally believed that these two nations had the merit of originating and establishing its manufacture. It is a remarkable circumstance that glass lenses have been found during the recent researches in the ruins of Nineveh. The Athenian ambassadors, in order to give an idea of the magnificence displayed at the court of the great king of Persia, said that they drank in cups of glass and gold. Some writers affirm that the Egyptians, in some instances, sealed up their dead in a coating of glass; and glass houses are said to have been not uncommon in that wonderful country. Some authors ascribe, with very plausible reason, the discovery of glass-making to the priests of Vulcan at Thebes and Memphis, the greatest chemists in the ancient world. The Egyptians are also known to have made enamels of divers hues which they applied on pottery, magnificent specimens of which are still extant, and are called Egyptian porcelain. These are chiefly covered with a

beautiful blue or green tinge, and groups of flowers or other designs are traced in black. Glass beads and other ornaments made of that substance, skilfully manufactured and beautifully tinged, have been found adorning mummies, which are known to be upwards of three thousand years old. It is certain that Tyre, Sidon, and Alexandria were long celebrated for their glass, and furnished the greater proportion of that used at Rome. Under the Roman empire the Egyptians still preserved their superiority in the art of glass-making, and it is said that AURELIAN caused them to pay their tribute in that manufacture. ADRIAN mentions that he had received drinking-glasses of various shades from a priest of a famous temple in Egypt, and gives instructions that they are not to be used but on the greatest occasions, and on the most solemn feast days. To these places the art was exclusively confined for some centuries, and glass was used as an article of luxury, being chiefly in the form of urns or drinking cups of the most elaborate workmanship, and exquisitely embellished with raised, chased, or ornamented figures. The Barberini or Portland vase, composed of a deep azure glass, with figures of a delicate white opaque substance raised in relief, is a splendid specimen, and was found in the tomb of ALEXANDER SEVERUS.

Sir J. G. WILKINSON adduces three distinct proofs that the art of glass-working was known in Egypt before the exodus of the children of Israel from that land, three thousand five hundred years ago. At Beni Hassan and at Thebes are paintings representing, in a very rude form, glass-blowers at work; and from the hieroglyphics accompanying them, it is found that they were executed in the reign of a monarch who occupied the throne at about that period. It is certain, moreover, that at that time images of glazed pottery were common, the vitrified material of which is of the same quality as glass; and, therefore, the mode of fusing, and the proper proportions of the ingredients for making glass, must have been already well known. Lastly, Sir J. G. WILKINSON adduces the instance of a glass bead about three-quarters of an inch in diameter, which Captain HENRY found at Thebes, and which contains in hieroglyphic characters the name of a monarch who lived fifteen hundred years before CHRIST. The knowledge of the manufacture probably travelled from Egypt to Greece, thence to Rome and modern Europe; and successive improvements have not only brought the art to a high degree of excellence, but have led to its subdivision into several kinds, such as flint-glass, plate-glass, window-glass, and green or bottle-glass making.—*Dodd.*

The art of glass-making seems to have been introduced into Italy by the Romans after their conquests in Asia, in the time of CICERO, and the first glass-works there were said to have been near the Flaminian Circus. It is highly probable that the workmen were imported from Egypt. The use of glass seems to have rapidly extended, and to have become very common. One of the emperors in the third century of the Christian era says, that he was disgusted with an article so mean and vulgar as glass, and that he would only drink from vessels of gold. By this time the manufacture of glass was so considerable that an impost was laid on

it, and it was extensively employed in the decorations of buildings. In glass mosaics particularly were combined the most brilliant colors.

From the circumstance of colored glass beads and amulets having been found among Druidical remains in this country, says BALLANTYNE, it has been argued by PENNANT and others, that the art of making glass was known in Britain before its invasion by the Romans. It can hardly be believed, however, that a people who had made very trifling advances in civilization, and who, it is known, were entirely unacquainted with any other art, should be found not only conversant with the use of glass, a complicated and highly ingenious process, but should excel in it; for the beads and amulets spoken of are of exquisite workmanship, and beautifully colored in imitation of the rarest and most precious stones. There seems little doubt, therefore, that the ancient Britons procured these in their traffic with the Syrians, who visited this island, as the modern Britons and other civilized nations visit the South Sea islands, to drive a trade with their savage inhabitants in toys and trinkets, giving these in exchange for skins or other natural productions. By whatever means, however, these ornaments came into Britain, it is certain that they were in extensive use, though principally for superstitious purposes, long prior to the Roman invasion, as they are found in barrows or tumuli of a much older date. One at Stonehenge, in particular, on being opened, was found to be filled with them.

Glain Neidyr, or druidical glass rings, generally about half as wide as our finger rings, but much thicker, have frequently been found. The vulgar superstition regarding these was, that they were produced by snakes joining their heads together and hissing, when a kind of bubble like a ring was formed round the head of one of them, which the others, continuing to hiss, blew upon till it came off at the tail, when it immediately hardened into a glass ring. Success was thought to attend any one who was fortunate enough to find one of those snake stones. They were evidently beads of glass employed by the Druids, under the name of charms, to deceive the vulgar. They are usually of a green hue, but some of them are blue, and others variegated with wavy streaks of blue, red, and white.

Glass utensils have been found in Herculaneum, which city was destroyed by an eruption of Mount Vesuvius in the reign of TITUS. A plate of glass also found there has occasioned much speculation as to its uses. Similar plates, to which PLINY gives the name of *vitrea camerae*, seem to have been employed in a manner not now very well understood, as panelling for their rooms. It is certain that two panes of glass were found in a window in Herculaneum.

In the reign of TIBERIUS, a company of glass manufacturers established themselves in Rome, and they had a street assigned them near the Porta Capena. The articles of their manufacture were few in number, and of inferior quality; neither did they make rapid improvements in their art, notwithstanding the large prices which were then given for glass of foreign manufacture in the imperial city. In the year 220, they had increased so much in importance, and the product was so considerable, that an impost was laid on it by

ALEXANDER SEVERUS. DION CASSIUS and PETRONIUS ARBITER concur in their account of the discovery of malleable or ductile glass by a celebrated Roman architect, whose success in the restoration to its position of a portico which leaned to one side, had roused the envy and jealousy of TIBERIUS, and occasioned his banishment from Rome. Thinking that his discovery would disarm the Emperor's wrath, the artist appeared before him bearing a glass vessel, which he dashed upon the ground. Notwithstanding the violence of the blow, it was merely dimpled, as if it had been brass. Taking a hammer from his breast, he then beat it out into its original shape; but instead of giving him the reward which he had expected, the Emperor ordered the unfortunate artisan to be beheaded; remarking, that if his discovery were known, gold would soon be held of as little value as common clay. This is probably another version of the story told by PLINY, of an artificer who made the same discovery, and whose workshop was demolished by those who had an interest in preventing the introduction of an article which would lower the value of gold, silver, and brass. Although it might not be justifiable to give unqualified discredit to these tales, yet the knowledge at present possessed would restrict the possibility of such a discovery within the narrowest limits. The union of the properties of malleability and vitrification seems to be incompatible. Some metallic substances, by the application of intense heat, are reduced to the state of glass, but at the same time lose their malleability; which fact would seem to imply that it is impossible to communicate the latter property to glass. The extraordinary stories above-mentioned have, however, been rationally enough explained by modern chemists. It has been observed by KUNCKEL, that a composition having a glassy appearance, and sufficiently pliant to be wrought by the hammer, may be formed; and by NEUMANN, that, in the fusion of chloride of silver, a kind of glass results, which may be shaped or beaten into different figures, and may be pronounced in some degree ductile. BLANCOURT mentions an artist who presented a bust of ductile glass to the Cardinal RICHELIEU; but he does not seem to have been more fortunate than his predecessors; for he was doomed to imprisonment for life, for the *politic reason*, as BLANCOURT with much simplicity observes, which led the Cardinal to fear lest the established interests of French glass manufacturers might be injured by the discovery. From expressions used by BLANCOURT in other parts of his work, it is thought that by malleable glass, such as was produced by this artist, he understood some composition similar to those which KUNCKEL and NEUMANN discovered, and was not very exact in limiting the term to that vitreous substance which is now generally understood when glass is mentioned.

The precise period at which the making of window-glass was introduced, is not now certainly known. Roman windows were filled with a semi-transparent substance called *lapis specularis*, a fossil of the class of talcs, which readily splits into thin smooth laminae, or plates. This substance is found in masses of ten or twelve inches in breadth, and three in thickness; and,

when sliced, very much resembles horn, instead of which it is to this day often employed by lantern-makers. The Romans were chiefly supplied with this article from the island of Cyprus, where it abounds. So good a substitute for glass is it said to have been, that, besides being employed for the admission of light, it was also used in the construction of hothouses, for raising and protecting delicate plants; so that, by using it, the Emperor TIBERIUS had cucumbers at his table throughout the whole year.

There is no positive mention of the use of glass for windows before the time of LACTANTIUS, at the close of the third century. But the passage in that writer which records the fact, also shows that the *lapis specularis* still retained its place. Glass windows are distinctly mentioned by St. JEROME, as being in use in his time. A century later, the windows of the church of St. SOPHIA at Constantinople are represented, by PAULUS SILENTIARIUS, as being filled with glass. After this period, frequent mention is made of them. JOANNES PHILIPPINUS states that glass was fastened into the windows with plaster.

BEDE asserts that glass windows were first introduced into England in the year 674, by the Abbot BENEDICT, who brought over artificers skilled in the art of making window-glass, to glaze the church and monastery of Wearmouth. Other authorities attribute the introduction of this luxury to Bishop WILFRED, junior, who died in 711. It would thus appear, that glass windows were first seen in England either about the seventh or the beginning of the eighth century. The use of window-glass, however, was then, and for many centuries afterwards, confined entirely to buildings appropriated to religious purposes; but, in the fourteenth century, it was so much in demand, though still confined to sacred edifices and ornamental purposes, that glazing had become a regular trade. This appears from a contract entered into by the authorities of York Cathedral in 1338, with a glazier, to glaze the west windows of that structure; a piece of work which he undertook to perform at the rate of sixpence per foot for white glass, and one shilling per foot for colored. Glass windows, however, did not become common in England till the close of the twelfth century. Until this period they were rarely to be found in private houses, and were deemed a great luxury, and a token of great magnificence. The windows of the houses were, till then, filled with oiled paper or wooden lattices. In cathedrals, these, and sheets of linen, supplied the place of glass till the eighth century; in meaner edifices, lattices continued in use till the eighteenth.

The glass of the Venetians was superior to any made elsewhere, and for many years commanded the market of nearly all Europe. Their most extensive glass-works were established at Murano, a small village in the vicinity of Venice; but the produce was always recognized as Venetian glass. Baron von LOWHEN states that, so useful were the glass-makers at one period in Venice, and so great the revenue accruing to the republic from their manufacture, that, to encourage the men engaged in it to remain in Murano, the senate made them all burgesses of Venice,

and allowed the nobility to marry their daughters; whereas, if a nobleman married the daughter of any other tradesman, the issue were not reputed noble.

The skill of the Venetians in glass-making was especially remarkable in the excellence of their mirrors. BECKMANN, who has minutely investigated the subject, is of opinion that the manufacture of glass mirrors certainly was attempted, but not with complete success, in Sidon, at a very early period; but that they fell into disuse, and were almost forgotten until the thirteenth century. Previously to this period, plates of polished metal were used at the toilette; and in the rudeness of the first ideas which suggested the substitution of glass, the plates were made of a deep black color to imitate them. Black foil even was laid behind them to increase their opacity. The metal mirrors, however, remained in use long after the introduction of their fragile rivals; but at length they wholly disappeared—a result effected chiefly by the skill of the Venetians, who improved their manufacture to such a degree, that they speedily acquired a celebrity which secured an immense sale for them throughout all Europe.

From Italy the art of glass-making found its way into France, where an attempt was made to rival the Venetians in the manufacture of mirrors. The first essay was unsuccessful; but another, made under the patronage of the celebrated COLBERT, in which French workmen who had acquired a knowledge of the art at Murano were employed, had better fortune. But a few years afterwards, this establishment, which was situated in the village of Tourlaville, near Cherbourg, in Lower Normandy, was also threatened with ruin by a discovery or rather improvement in the art of glass-making, effected by one ABRAHAM THEVART. This improvement consisted in casting plates of much larger dimensions than it had hitherto been deemed possible to do. THEVART's first plates were cast at Paris, and astonished every artist by their magnitude. They were eighty-four inches long and fifty inches wide, whereas none previously made exceeded forty-five or fifty inches in length.

In 1695 the two companies, THEVART's and that at Tourlaville, united their interest, but were so unsuccessful, that in 1701 they were unable to pay their debts, and were, in consequence, compelled to discharge most of the workmen, and abandon several of their furnaces. Next year, however, a company was formed, under the management of ANTOINE D'AGINCOURT, who re-engaged the discharged workmen; and the works realized considerable profits to the proprietors—a circumstance which is attributed wholly to the prudent management of D'AGINCOURT.

Early in the fourteenth century, the French government made a concession in favor of glass-making, by decreeing, that not only should no derogation from nobility follow the practice of the art, but that none, save gentlemen or the sons of noblemen, should venture to engage in any of its branches, even as working artisans. This limitation was accompanied by a grant of a royal charter of incorporation, conveying important privileges, under which the occupation became eventually a source of great wealth to several families of distinction.

It has been said that the manufacturing of window-glass was first introduced into England in the year 1557. But a contract quoted by HORACE WALPOLE proves that this article was made in England upwards of a century before that period. This curious document is dated 1439, and bears to be a contract between the Countess of WARWICK and JOHN PRUDDE of Westminster, glazier, whom she employed, with other tradesmen, to erect and embellish a magnificent tomb for the Earl, her husband. JOHN PRUDDE is thereby bound to use no glass of England, but glass from beyond seas; a stipulation which, besides showing that the art of making window-glass was known and practised in England in the fifteenth century, seems also to indicate that the article made was inferior to what could be obtained from abroad. The finest sort of window-glass was first made at Crutched Friars, London, in 1557. The first flint-glass made in England was manufactured at the Savoy House, in the Strand; and the first plate-glass, for looking-glasses, coach windows, and similar purposes, was manufactured at Lambeth by Venetian workmen, brought over in 1670 by the Duke of BUCKINGHAM. From that period the English glass manufactories, aided by the liberal bounties granted them in cash upon glass sold for export, became powerful and successful rivals of the Venetian and French manufactories. The bounty on glass exported, which the government paid to the manufacturer, was not derived from any tax by impost or excise previously laid; for all such were returned to the manufacturer, together with the bounty, thereby lessening the actual cost of the article from twenty-five to fifty per cent., and enabling the English exporter to compete successfully in foreign markets. This bounty provision was annulled during the premiership of Sir ROBERT PEEL, together with all the excise duty on home consumption.

The art of glass-making was introduced into Scotland in the reign of JAMES VI. An exclusive right to manufacture it within the kingdom, for the space of thirty-one years, was granted to Lord GEORGE HAY in the year 1618. This right his lordship transferred in 1627, for a considerable sum, to THOMAS ROBINSON, merchant-tailor in London, who again disposed of it for two hundred and fifty pounds to Sir ROBERT MANSELL, vice-admiral of England. The first manufactory of glass in Scotland, an extremely rude one, was established at Wemyss, in Fife. Regular works were afterwards commenced at Prestonpans, Leith, and Dumbarton.

Crown-glass is now manufactured at Warrington, St. Helen's, Eccleston, Old Swan, and Newton, Lancashire; at Birmingham, Hunslet, near Leeds, and Bristol. It is also fabricated of excellent quality on the Tyne and Wear. Great improvements have recently been made in the manufacture of crown-glass, and it is asserted that this article, as made in England, is superior in quality to that of any other nation.

According to BALLANTYNE, the manufacture of glass was introduced into the American States in 1790, by ROBERT HEWES, a citizen of Boston, who erected a factory in the then forest of New Hampshire. The chief aim of Mr. HEWES was to supply window-glass, but he did not succeed. Another attempt was made in 1800, when a factory was built at Boston for making

crown window-glass; but this was also unsuccessful, till a German named LINT, in 1803, took charge of the works, and the state of Massachusetts agreed to pay the proprietors a bounty on every table of window-glass they made, after which the manufacture was carried on successfully, the glass steadily improving in quality, and becoming famed through all the States as Boston window-glass. The same company erected new and more extensive works at Boston. The mystery attached to the art of glass-making followed it into America. The glass-blower was considered a magician, and myriads visited the newly-erected works, looking on the man who could transmute earthy and opaque matter into a transparent and brilliant substance, as an alchemist who could change base metal into gold.

Since the manufacture of flint-glass originated in the Eastern States, there have been above forty companies formed from time to time, nearly thirty of which have proved failures. There are now ten in operation, two of which are at East Cambridge, three at South Boston, one at Sandwich, three near New York city, and one at Philadelphia. Forty-eight thousand tons of coal, six thousand five hundred tons of silica, two thousand five hundred tons ash, nitrate of soda, *et cetera*, and three thousand eight hundred tons of lead, are annually consumed in the manufacture of flint-glass.

In the vicinity of Pittsburgh, in the Western States, are nine manufactories of flint-glass, and ten of window-glass, and in the river towns are fifteen window-glass factories.

There is good reason for supposing that the art of staining or painting glass is coeval with the art of making glass itself, since, as will be afterwards seen, it is difficult to make it without color. The possibility of subjecting this propensity to the will of the manufacturer must have very obviously presented itself, although it certainly requires much art and chemical knowledge to produce perfect specimens of this description of manufacture. This perfection seems, however, to have been attained at a very early period. It is certain that the art was known in Egypt three thousand years ago. The beautiful imitations of precious stones found adorning mummies which are known to have existed for that time have been already noticed; and frequent mention of specimens of Eastern workmanship of consummate beauty are met with, upon which great value was placed. Allusion has also been made to the fact, that the Emperor ADRIAN, whilst at Alexandria, was presented, by an Egyptian priest, with two glass cups, which sparkled with hues of every kind, and which had been used in the service of the temple—a present so highly prized by the Emperor, that he ordered them to be produced only on festivals and great solemnities. The works of CAYLUS and WINKELMANN furnish some striking instances of ancient skill in the formation of pictures by means of delicate glass fibres of various hues, which, after being fitted together with the utmost nicety, were conglutinated by fusion into a solid mass. The art of combining the various tints, so as to produce pictures in the manner now practised, is comparatively of recent date. The earliest specimens of this kind of work discover a factitious joining of different pieces of glass, differently tinted, and so ar-

ranged as, by a species of mosaic work, to produce the figure or figures wanted. The various pieces are held together generally by a vein of lead, run upon the back of the picture, precisely at their junction.

But modern ingenuity has superseded this clumsy expedient; and every color used in painting can now be introduced into one entire sheet. For a long period the pictured glass used in cathedrals was merely painted on the surface, the art of incorporating the tints with the glass by fusion, the method now practised, being unknown till the beginning of the fifteenth century. This great improvement is ascribed to a painter of Marseilles, who went to Rome during the pontificate of JULIUS II.; but his discovery went no further than the producing of different colors on different pieces of glass, and having them afterwards united in the old fashion. This art was, at a later period, greatly improved by ALBERT DURER and LUCAS of Leyden, the latter of whom brought it nearly to the state of perfection in which it now exists.

The first painted glass executed in England was in the time of King JOHN; previous to this, all stained or painted glass was imported from Italy. The next notice of it occurs in the reign of HENRY III. The treasurer of that monarch orders that there be painted, on three glass windows in the chapel of St. JOHN, a little Virgin Mary holding the Child, and the Trinity, and Saint John the Apostle. Some time after he issues another mandate for two painted windows in the hall.

Even at this early period, however, England boasted of eminent native artists in glass painting, amongst the first of whom was JOHN THORNTON, glazier of Coventry. This person was employed, in the time of HENRY IV., by the dean and chapter of York cathedral, to paint the eastern window of that splendid edifice; and for the beautiful and masterly workmanship which he exhibited in this specimen of skill, he received four shillings per week of regular wages. He was bound to finish the work in less than three years, and to receive, over and above the weekly allowance, one hundred shillings for each year; and if the work was finished to the satisfaction of his employers, he was to receive, on its completion, a further sum of ten pounds. It must be recollected that the value of money was at that time much higher than in modern days.

From this period downwards there have been many skilful native artists, although the Reformation greatly impeded the progress of the art, by banishing what was deemed the ungodly ostentation of ornamented windows from churches; indeed, so serious was this interruption, that the art had nearly altogether disappeared in the reign of ELIZABETH. Amongst the most eminent glass painters who first appeared upon the revival of the art, were ISAAC OLIVER, born in 1616, and WILLIAM PRICE, who lived about the close of the seventeenth century. This last person was for many years the only glass painter in England. He is said to have discovered, what is to this day a desideratum in the art of glass staining, the secret of producing a rich, clear, bright, and transparent red, the most difficult to strike, and the most expensive of all the hues employed in glass painting. But PRICE having died soon after making this discovery, his secret was never divulged. This

artist was succeeded by a person at Birmingham, who, in 1757, fitted up a window for Lord LYTTLETON, in the church of Hajely. To him succeeded one PECKIT of York, who attained considerable eminence in the art.

During all this time, however, and indeed until a comparatively recent date, painted glass was regarded as too costly and too magnificent an article to be otherwise employed than in decorating religious edifices, or the palaces of nobles; and even in the latter case was but sparingly used. Modern improvement has now placed this beautiful ornament within the reach of very ordinary circumstances; and when this is considered, it must excite a strong feeling of surprise to find how little so elegant a luxury is even yet in demand. The art of staining glass is now practised with very great success. The colors of modern artists, notwithstanding what is often urged to the contrary, equal in variety and richness those of the ancients; and, with the superior knowledge which is now possessed of the principles of drawing, and of bringing several colors together on a single sheet, encouragement alone is wanting to attract artists of talent and inventive genius to the pursuit of the art, and to carry it to a greater degree of excellence than it has ever reached in the hands of their predecessors.—*Encyclopædia Britannica*.

NATURE AND COMPOSITION OF GLASS.—The researches of BERZELIUS having removed all doubts concerning the acid character of silica, the general composition of glass now presents no difficulty of conception. This substance is the product of fusion at a high temperature of silica, or silicic acid, sometimes of boracic acid, with different salifiable bases, as potassa, soda, lime, magnesia, baryta, oxide of lead, oxide of tin, protoxide of iron, protoxide of manganese, alumina, and the sesquioxide of iron, and binoxide of manganese; the product solidifies after fusion in the form of a transparent mass, which is either colorless or not, according to the ingredients which it contains; it combines a great degree of hardness with the property of resisting the destructive action of air, water to a certain extent, and even that of the more powerful chemical agents.

It is well known that silica acts the part of a powerful acid at the temperature of a red heat, and is capable of expelling carbonic acid, hydrochloric acid, *et cetera*, from compounds, and combining with the bases named above, giving rise to solid combinations. Glass, in short, is a true salt—a silicate, and is an artificial production of a similar character to those compounds which occur so abundantly in nature; it differs, however, from these in one essential particular, that it possesses a distinctly non-crystalline structure; or is, as it is scientifically termed, *amorphous*. Glass, as is well observed by KNAPP, may be said to bear the same relation to a natural silicate of like composition, that melted sugar does to the ordinary crystallized substance.

Special Effect of the Different Constituents.—Although, in a purely chemical view, the potassa, soda, lime, oxide of lead, alumina, and oxide of iron, perform the same part, it is, nevertheless, very evident that, in practice, the employment of one of these bodies cannot be substituted indifferently for that of one or other of its analogues. There necessarily results in the product differences of fusibility, of ductility, of hardness, *et cetera*,

which must be taken into consideration. Hence the necessity of classing glasses according to their composition and properties. This classification will be given afterwards. In the meantime, the characteristic effect of the different constituents on the nature of the glass may be briefly stated:—

The *silicates of soda and potassa* are the most fusible, and so much the more in proportion to the greater amount of the alkaline bases. One part of silica with two to three of potassa or soda, produces a glass which is fusible at a cherry-red heat, and soluble in cold water. Equal parts of alkali and silicic acid—silica—form a glass readily fusible, but imperfectly soluble. One equivalent of soda or potassa combined with six equivalents of silicic acid, and therefore represented by the formula,

yield a compound fusible only by the heat of a very powerful forge. Potassa is more efficacious than soda in rendering the glass easy of fusion. A more brilliant lustre results from the use of soda, but at the same time a bluish-green tint is communicated to the glass. No coloring action is exerted by potassa; but the brilliancy of the glass is somewhat diminished by it.

The *silicates of lime* are much less fusible than those of the alkalis. The most fusible of the former, represented by the formula $\text{Ca O} + \text{Si O}_3$, requires for its fusion the violent heat of a forge. The others, represented by

are only softened at the same temperature; the corresponding *silicates of magnesia* are not more fusible. Lime increases the hardness of the glass, and adds more to its lustre than the alkalis, without coloring the produce.

The *silicates of alumina* are still more refractory than the preceding. The least infusible, represented by $\text{Al}_2 \text{ O}_3$, 3 Si O_3 , is scarcely softened in the heat of a furnace. Of all the ingredients, alumina exerts the most powerful effect in increasing the difficulty of fusion.

The *silicates of the protoxides of iron and manganese* are more fusible than those of lime and magnesia, especially when they consist of one equivalent of each ingredient, thus—

The silicate of protoxide of iron has a dark-green color, but may be decolorized by bringing it to the state of a silicate of the sesquioxide; this is effected by adding a small quantity of binoxide of manganese. Care must be taken not to add it in excess, for in this case it would communicate a violet color to the glass. The binoxide, Mn O_2 , when added in small quantity, is converted into protoxide, Mn O ; but if any excess has been employed, it becomes reduced at a red heat to sesquioxide, $\text{Mn}_2 \text{ O}_3$, and produces a deep amethystine red glass.

The *silicates of the oxides of lead* are the more fusible in proportion to the greater amount of the base. With equal equivalents, the silicate of lead, $\text{Pb O} +$

SiO_2 , melts at a red heat. In fact, oxide of lead exerts a directly opposite action to alumina, being a prominent ingredient in the easily fusible varieties of glass, which are also characterized by great softness, a high brilliancy, perfect absence of color, and by the property of refracting light more powerfully than any other kind. The silicates of the oxide of zinc present analogous properties.

Baryta also exerts a similar, although less energetic action than lead.

These different silicates react on one another, and reciprocally modify each other; in composition, they become more stable, less fusible, and less subject to crystallize. Hence the advantage of the complex proportions employed in the glass and crystal manufactures.

When *boracic acid* is added, it forms boro-silicates, often more fusible, more ductile, easier to work, and producing less waste, especially in table-ware and plate-glass manufacture. M. PAYEN remarks that the experiments undertaken by MM. MAES and CLEMANDOT on crystal, with a base of oxide of zinc, yielded products remarkable for their whiteness, their transparency, their hardness, and the brilliant reflection of their cut faces.

In the words of KNAPP, it follows, as a general conclusion, from what has been stated, that those varieties of glass which possess the highest degree of lustre and power of refraction, will also be the softest—that is, the most easily scratched. They are likewise those which exhibit the highest specific gravity—from 2.8 to 3.6—and, as might be deduced from that circumstance, they—at least as far as the colorless glasses are concerned—are those which contain bases with a very high atomic weight—oxide of lead, baryta. Those bases, on the contrary, which render the glass hard and durable, appear to produce little lustre or power of refraction. The specific gravity of these varieties lies between 2.37 and 2.56. Strictly speaking, the alkalies, lime, and oxide of lead, are the only bases expressly contained in the mixture for the manufacture of glass, without reference to the different coloring and decoloring matters. Magnesia sometimes accompanies the lime, and enters, but in small quantity only, into the composition of the glass. Alumina and oxide of iron are, in like manner, only casual constituents, being contained as impurities in the other ingredients. Even in those cases where these two bases enter in large quantities into the composition of glass, they are never expressly added to the mixture; but are always derived from the impure materials. Thus, in the manufacture of ordinary bottle-glass, where color is of no moment, substances containing iron and alumina are employed. The origin of the small quantity of alumina which is found in glass that should properly be free from it, must be traced to the sides of the pots or crucibles in which the glass has been fused.—*Knapp*.

The metallic oxides which have not been mentioned, as those of gold, silver, copper, give rise to a great variety of intense colors, and are consequently used in the manufacture as pigments.

Commercial varieties of Glass.—Before proceeding to a more minute inquiry into the physical and chemi-

cal properties of glass, as these are affected by differences either in the ingredients or their properties, or in the processes followed, it will be proper to place before the reader a summary view of the characters and composition of the different varieties of glass, as preliminary to a more detailed exposition, not only of the special properties, but also of the special manufacture of each of these varieties.

There is much difficulty in dividing the glasses according to any definite principle. One of the simplest arrangements is given by TOMLINSON, as follows:—

1. Silicate of potassa and oxide of lead. Examples:—*Flint-glass, crystal, and strass*.

2. Silicate of soda and lime; or silicate of potassa, soda, and lime. Examples:—*Common window, English crown, and plate*.

3. Silicate of potassa and lime. Examples:—*Foreign crown, refractory Bohemian glass*.

4. Silicate of soda, lime, alumina, and oxide of iron. Example:—*Coarse green wine-bottle glass*.

The following arrangement, somewhat similar to that proposed by KNAPP, will form the basis of that adopted in the present article, beginning, as a general rule, with the coarser, and advancing by a pretty regular gradation to the finer or rarer varieties.

1. BOTTLE-GLASS, or what is more properly described by the German term *Hohlglase*, or *Hollow glass*, comprises all glass worked into the form of vessels or tubes. According to the purity of the *metal*, which is the technical term given to glass in the fused state, this variety is subdivided into different qualities, such as—*Ordinary bottle-glass*, consisting of silica, potassa or soda, lime, alumina, and oxide of iron; *glass used for medicinal bottles*, consisting of silica, soda, lime, some alumina, and a very little protoxide of iron; *white bottle-glass* for bottles or phials, tumblers, tubes—containing silica, soda or potassa, and lime. It is evident, therefore, that under the general term *Bottle-glass* or *Hohl-glass*, are included different vitreous compositions. Its distinguishing characteristic, as applied to ordinary bottle-glass, is the presence of protoxide of iron; and therefore it may be described, in general terms, as a silicate of potassa or soda, of lime, of alumina, and oxide of iron.

2. WINDOW-GLASS, including *English crown* and *cylinder* or *sheet-glass*: this is a silicate of potassa or soda, lime, and alumina.

3. PLATE-GLASS, composed of silica, soda, or potassa, lime, and a little alumina. This variety only differs from the preceding by the greater purity and freedom from color of the materials.

4. FLINT-GLASS, used for grinding, *et cetera*, composed of silica, potassa, and oxide of lead.

5. CRYSTAL, for optical purposes and table-ware, consists of silica or boracic acid, potassa, and more lead than the preceding. In short, it is a simple flint-glass, formed with very pure materials.

6. STRASS, or the substance composing the imitation of precious stones, known as paste, consists of silica, potassa, with a still larger amount of oxide of lead, and colored by various materials.

7. ENAMEL, a silicate and stannate or antimoniate of potassa or soda, and of oxide of lead. It may be other-

wise described as composed of silica, soda or potassa, and oxide of lead,—rendered opaque by oxide of tin or antimony.

8. **SOLUBLE GLASS**, which is a simple silicate of potassa or of soda, or a mixture of these two silicates.

The manufacture, the distinguishing properties, and the special applications of these different kinds of glass, will be described afterwards. *Strass* and *enamel* have been already treated under the latter head, and will, therefore, be only briefly alluded to in the present article. The *soluble glass*, which is used only for special purposes, such as a protective varnish for pictures, a fireproof coating for building-materials, *et cetera*, is scarcely entitled to be ranked as a true glass; but its character and applications will be stated in a future page. In the meantime, the following tables, which are given by KNAPP, with notes by RICHARDSON and RONALDS, will be found useful for reference, as showing the proportional composition of the more important glasses according to different analysts of high authority:—

BOHEMIAN GLASS.—The Bohemian flint-glass is distinguished from the others by containing no lead.

Mr. ROWNEY has lately analysed the Bohemian hard glass tubing, so indispensable to chemists in the prosecution of researches in organic chemistry, and finds it to be essentially a silicate of lime and potassa, in which the oxygen in the silicic acid is to that contained in the bases as 6 to 1. Analysis yielded:—

	Centasimally represented.
Silica,	73.0
Potassa,	11.5
Soda,	3.0
Lime,	10.5
Magnesia,	—
Alumina,	—
Sesquioxide of iron,	2.0
Oxide of manganese,	—
	100.0

It may, however, be remarked, that this tubing is by no means of uniform composition, as all who have been much occupied with organic analysis will have found to their cost; some tubes being much more fusible than others.

The opal is very similar to hyalite, *muller glass*, a hydrate of silica. The composition is remarkable: it is a simple silicate of potassa, which, from being imperfectly melted, remains semi-transparent, with pieces of quartz dispersed through the mass. It does not attract moisture, and is not attacked by boiling water. It differs from FUCH's soluble glass, by containing ten per cent. more silica.

The Venetian contains also traces of magnesia and phosphoric or boracic acid; the crystals appear disseminated through the mass, which is of a yellow tint, and transparent in thin sheets. The tin and iron obviously assist in the formation of the crystals of metallic copper, after which the tin becomes silicate of the protoxide, otherwise the glass would become opaque.

The oxide of lead which is used in the manufacture of crystal, is not the protoxide commonly known as *massicot*, and represented by the formula PbO , but *minium*, which is a sesquioxide, Pb_2O_3 ; for, as BAR- RUEL remarks, one may depend on the latter not being mixed with metallic lead, which almost necessarily happens with the *massicot* of commerce. The object of employing oxide of lead in this kind of glass is to increase the density, and, consequently, the refractive power, which gives the glass a peculiar lustre or brilliancy.

Chemical Constitution of the Different Glasses.—From a careful inspection of the preceding tables, it will be seen that all the constituents of the different varieties of glass are in a state of chemical combination. It follows that the individual constituents must be united in equivalent proportions; and though these relations are sometimes difficult to trace, in consequence of different oxides replacing each other, still, the regularity of the composition is always shown by the existence of a simple relation between the collective amount of oxygen in the bases, and that contained in the silica or silicic acid. The combination in definite proportions is rendered more obvious, as KNAER observes, when the empirical formulæ are deduced from the composition in 100 parts. Thus, by referring to the numbers of the columns in the preceding tables, the composition in 100 parts of each of the glasses specified, will be represented as follows:—

Bottle-glass, No. 5,	corresponds to	$\text{KO} + 8 \text{CaO} + 2 \text{Al}_2\text{O}_3 + \text{F}_2\text{O}_3 + 8 \text{SiO}_3$;
Window-glass, No. 2,	"	$3 \text{NaO} + 5 \text{CaO} + 12 \text{SiO}_3$;
Plate-glass, No. 1,	"	$2 \text{NaO} + \text{CaO} + 6 \text{SiO}_3$;
White Crown-glass, No. 5,	"	$\text{KO} + \text{CaO} + 3 \text{SiO}_3$;
Crystal, No. 2,	"	$\text{KO} + 2 \text{PbO} + 8 \text{SiO}_3$;
Flint-glass, No. 2,	"	$6 \text{KO} + 9 \text{PbO} + 20 \text{SiO}_3$;
Strass, No. 1,	"	$3 \text{KO} + 9 \text{PbO} + 16 \text{SiO}_3$; <i>et cetera.</i>

KNAPP further justly remarks, that although more probable suppositions may be formed with reference to the manner in which the silica is divided amongst the bases, and although the preceding calculations do not lead to any rational formulæ, yet the knowledge of the empirical composition for any species of glass, as represented in the examples above given, is nevertheless a very valuable guide in mixing the ingredients for its manufacture, and of great service in improving or correcting the prescribed rules.

Comparative Fusibility of the Glasses.—Under the influence of a cherry-red heat and upwards, the different kinds of glass are all capable of being first softened and then undergoing a complete fusion. At the same time, the difficult fusibility of the bi and tri silicates, or those in which the acid preponderates, and the opposite properties of those which contain a larger proportion of base, are very important facts in connection with the manufacture of glass. Silicic acid *per se*, is perfectly infusible in every furnace, but it acquires the property of fusibility in a greater or lesser degree, according to the quantity of base with which it is mixed. Glass-makers, in short, call all the bases *fluxes*, and are well aware that the work is facilitated and fuel saved by increasing the amount of flux in the mixture; but, at the same time, they know that the addition of flux cannot exceed a certain limit without detriment to the durability of the glass. When glass is attacked by reagents, under ordinary circumstances, it is always a result of the removal of base; but this is a subject for future consideration. As already stated, glasses with a lead base are the most fusible, and the more so in proportion as they contain a more considerable quantity of oxide of lead. Common glasses, on the contrary, are less so, the more lime and alumina they hold. Thus, strass, flint-glass, and crystal, are more fusible than common or window-glass, and the latter is a little more so than bottle-glass.

Imperfect Fluidity of Glass.—The possibility of casting or moulding glass, as well as its purification, depends upon the fact that at very intense heats the so-called *metal* is tolerably fluid, though still possessing a consistence which may be compared to that of weak sirup. In this state the heavier impurities are enabled to subside to the bottom, while the bubbles of gas, which too often form flaws in glass, rise by their levity to the surface. At a brisk red heat, on the contrary, the metal is only in a semi-fluid state, and on this peculiar and valuable property depends the possibility of working it into every variety of form. In this state it is an exceedingly tough, thick mass, possessing great ductility, and capable of being drawn out into the finest threads, or blown into the form of the thinnest hollow spheres. In short, it is evident that the usual methods of working glass by *blowing*, and of soldering different pieces together by simple pressure or contact,

would be quite impracticable, unless the mass possessed these properties.

BRITTLINESS.—When glass has been heated to the softening point, and exposed to a rapid cooling, it is very brittle; when, on the contrary, it is submitted to a slow cooling, it becomes capable of resisting pretty severe shocks without breaking, and it stands equally well sudden variations of temperature. These phenomena have been compared to the tempering of steel; and although the explanations which have been given of them are not quite satisfactory, yet it will be necessary to enter into some details, on account of the practical importance of the subject. The metamorphosis has been attributed to unequal crystallization. It will be seen afterwards that the particles of glass always exhibit in the fluid state a tendency to arrange themselves in a regular manner, and form crystals. Now, when the mass is cooled suddenly, no time is allowed the particles to follow this tendency, and they are forced, as it were, against their inclination to remain in that relative position towards each other which they assumed during the working, or, in other words, to form an amorphous mass. This forced relative position of the particles is greatest where the glass has been rapidly cooled; the interior of the mass is, therefore, not so subject to it as the surface, and this latter also contracts in a greater degree. The outer layers are, consequently, in a state of tension, with reference to those in the interior. It is obvious, from these facts, that there must be a want of uniformity in the attractions of the particles of glass for each other; that a tendency to subvert the force of cohesion has been induced, which the slightest impulse from without will be sufficient to call into action. This circumstance perfectly explains the brittle nature of glass, which sometimes rises to a very extraordinary degree. For example, if one takes a little melted glass, and allows it to fall, drop by drop, into cold water, each drop will suddenly solidify, and will take a form generally spheroidal or ovoidal, terminated by a tail which ends in a rapidly tapering point, *a*, as represented in Fig. 135. The surface of this drop of glass is harder than ordinary. But by merely breaking off the point, the

Fig. 135.

tension is called into play, and the whole mass flies to pieces, or rather is instantly converted into a fine powder, with a slight detonation. These little articles are known, from their great brittleness, under the name of *Rupert's drops*.

The effect is explained by DUMAS, by supposing that by the immersion in cold water the surface of the glass is suddenly solidified, the central parts being still fire-

red, and consequently much dilated. When these last become solidified and cooled down, they must have retained points of adherence to the surface, and consequently occupy a larger volume than that which agrees with the temperature to which they are reduced; the central molecules are, therefore, more distended than usual, and exert a powerful contracting force on the surrounding parts. At the instant when a part of the envelope or outer portion is broken, the molecules which had been retained by it briskly contract, draw in with them all the others, and thus determine a multitude of points of rupture; as this effect is instantaneous, each fragment is shot with force, and drives the air before it; this fluid, therefore, undergoes a sudden dilatation and contraction, from which results the detonation that is heard.

The same effect is produced under another form, in what is termed the *Bologna* or *philosophical phial*—Fig. 136. This is a kind of short tube, thick, and closed

Fig. 136.

at one end, which is obtained at crystal manufactories, by blowing a small portion of glass to judge of the state of the metal in the pots during the melting. These tubes are very thick, for they must be sufficiently so to allow of appreciating exactly the tint of the glass. They are exposed to a rapid cooling, because the object which they are intended to serve does not require that any care should be taken in that respect.

This cooling is even accelerated by shaking in the air the rod which supports the small tube. The latter is then, in point of fact, in a state very analogous to that of the Rupert drops, and DUMAS explains their remarkable brittleness in the same manner. The interior parts have undergone a slow, and the exterior parts, on the contrary, a rapid cooling; and when these tubes are struck, even very strongly, on the outside, they do not break, while the slightest stroke on the inside is sufficient to make them fly in pieces, with a detonation similar to that which occurs in the case of the Rupert drops. A small marble, a bit of glass allowed to fall into the interior of the tube, is sufficient to make it burst asunder.

Phenomena more or less analogous to these happen with glass vessels of some thickness, which are sold for common uses. By slight variations of temperature, such as occur when they are carried from a room without a fire into a warm room, it sometimes happens that these glasses suddenly burst without any apparent cause. It is obvious, that the thicker the glasses, the more readily will effects of this kind be produced. Tubes of glass somewhat thick, and especially those which are of unequal thickness, are also very subject to split, and usually the crack is prolonged through the whole length of the tube. But glass tubes are not submitted to that particular operation, the object of which is to render glasses less liable to break by sudden changes of temperature. This operation is termed *annealing*, and consists in submitting the glass to a very slow refrigeration. The details of the process will be described in connection with the general arrangements of the glass-house and its furnaces, among which the annealing arch or oven takes an important place.

It would seem that the ordinary annealing of glass, whether it be that the operation is badly performed, or that it has not a durable effect, always leaves something to be desired. For some articles, a method of annealing is employed which is very simple, but, at the same time, expensive, if required to be applied on a large scale. It consists in placing the glass vessels in a trough or pan, taking the precaution to separate them by a little hay or straw. The vessels and the pan are filled with water, and the liquid is brought to ebullition. The whole is then left to cool slowly. The vessels thus treated are, so to speak, insured against any rapid change of temperature, comprised within the interval of 180° Fahr., or thereabouts. By using a bath of water charged with some salt, an oil-bath, or a bath of fusible alloy, this method might be extended to higher temperatures.

The efficacy of the process rests on the great difference which exists between the conducting power of air and that of liquids. There is no doubt that in the operation of annealing in the air, different points of the surface are cooled at different rates, a circumstance which can never occur when the annealing is effected under a liquid mass. It is well known in laboratories, that vessels which have accidentally undergone an annealing of this kind, are thereby rendered very fit to support, without breaking, rapid changes of temperature.

On the whole, although the brittleness of glass is not entirely obviated by the most careful annealing, yet it is so modified that the vessels, with a little care, can be used for all ordinary purposes. Sudden change of temperature, or partial application of heat, will cause the fracture of unannealed glass quite as surely as a blow, by expanding it more at one part than another.

DEVITRIFIED, OR SEMI-CRYSTALLISED GLASS.—As excessive brittleness results from the sudden cooling of glass, so, on the other hand, when the fused metal is cooled too slowly, the amorphous state entirely disappears, the mass assumes a crystalline structure, and other changes occur which are termed *devitrification*. If the glass contain different bases, a partial separation takes place; the silica divides itself between the bases, and thus forms compounds of definite proportions which crystallize separately. In this case the intimate mixture of the materials which constitute the true glass is destroyed; the glass becomes *very hard, fibrous, opaque, much less fusible, a better conductor of electricity and of heat*. The first glass of this kind was produced and described by RÉAUMUR, and was termed by him *devitrified glass*.

The devitrification of glass is a general phenomenon, which exhibits itself in all kinds of glass, but especially in glass with several earthy bases, and more difficultly in plumbiferous glasses, or glasses simply alkaline. It is almost always produced by melting the glass, and allowing it to cool very slowly, or else by heating the glass to the softening point, and submitting it to a prolonged heat and a graduated cooling. The operation succeeds better in bottle-glass than in any others; then comes common green glass, next white glass, then simple glass, with a soda base; after this, flint-glass, and, lastly, simple glass, with a potassa base.

This property exerts so great an influence in the manufacture of glass, that it is difficult not to make an immediate application of it. It explains, indeed, why, in the making of bottles, so much care is taken to avoid the repeated reheating of the mass which is to be formed into that article. It would be thoroughly devitrified in a few seconds; the glass would become hard, difficult to fuse, and would present a multitude of solid grains disseminated in a matter still soft. One sees in the same manner why green glass, and even common white glass, and, still more so, bottle glass, can only be shaped by the lamp of the enameller when the work is performed with the necessary despatch. If he works so slowly that he is obliged to reheat several times the glass tube which he is blowing, the mass devitrifies, and all the phenomena show themselves which have just been described. In vain does he then try to blow a bulb—all the force of his lungs will not avail; the glass is no longer soft. Besides, the material then becomes rugous, semi-opaque, and almost infusible.

One can understand, on the same principles, how important it is to select with care glasses intended to be used in large and thick masses, such as those designed for the making of lenses for large optical instruments. The cooling of such masses is necessarily very slow, which induces the devitrification of the glass. It is almost impossible to succeed, therefore, except with glass having a base of lead and potassa, and glass with a base of potassa and lime. Indeed, these two kinds of glass, which constitute *flint* and *foreign crown* glass, are employed exclusively on the Continent for the making of objectives for achromatic telescopes.

The devitrification of glasses is a phenomenon of the greatest interest, and to which the attention of glass-makers cannot be too much directed. It will appear still more worthy of consideration when it is shown that, in virtue of its properties, devitrified glass is capable of replacing porcelain in almost all its uses. Thus, for the requirements of chemistry, one may make tubes, retorts, receivers, capsules, which resist the fire as well as vessels of porcelain, which are as impermeable as common glass, which resist acids very well, and which, in fine, may be obtained in a single piece, under a thousand diversified forms, which the moulding of porcelain could only furnish with difficulty. This is a business to be created, and a very important business, for it would furnish vessels of a wholesome, elegant ware, and at a comparatively low price.

To effect the devitrification of glass, RÉAUMUR selected common bottle or green glass. He filled the vessels with a mixture of roasted sulphate of lime and white sand, reduced to fine powder. He introduced them into an earthen box, which itself was filled with a similar mixture, taking care that the vessels were well isolated from each other, as well as from the sides of the box, the empty space being occupied with the plaster and sand. The box, thus prepared, fitted with a lid and luted, was carried into a pottery furnace, and left to itself during the whole duration of a firing. At the end of that time the glass was entirely devitrified.

The fracture of this glass is silky, and an attentive examination of it is sufficient to show how the phenomenon is produced. In fact, exactly in the middle of its thickness, the glass presents a brown line, and it is at this point that an infinite number of small crystalline needles meet, proceeding from the exterior and interior surface of the vessel. These needles, perfectly parallel to each other, are perpendicular to the surface of the glass, as well as to the plane passing through the line of junction, which itself follows all the variations of form in the glass. It may be added, that in glasses imperfectly devitrified the two surfaces exhibit similar needles, but too short to meet, and, consequently, separated by a greater or less breadth of common glass, which occupies the middle of the thickness of the plate or vessel. It is evident, therefore, that whatever cause determines the crystallization of the glass, acts first on the surfaces, and afterwards penetrates to the middle, till the crystals setting out from the two opposite points come to meet.

M. DARTIGUES was convinced that the gypsum and sand mixture was not indispensable, and that bottle-glass, heated only to redness during some hours, was entirely devitrified. Nevertheless, the potassa volatilizes during the devitrification, which indicates the utility of a silicious cement, which then performs the part of an absorbing body in the manner of the sulphuric acid in LESLIE's experiment for freezing water in a vacuum.

RÉAUMUR did not well understand the theory of the phenomenon of devitrification, and, subsequently, KEIR, PAJOT-DES-CHARMES, and some other observers, in examining and describing the crystallizations which sometimes occur in glass, were not more successful in perceiving the intimate connection between these two classes of facts. The researches of DARTIGUES as well as those of FLEURIAU DE BELLEVUE, ultimately placed beyond doubt the complete identity of these two phenomena.

Devitrification is therefore a crystallization of glass. Experience proves that glass, slowly cooled, almost always crystallizes when the passage from the liquid to the solid state is effected so gently as to allow the requisite molecular arrangements to take place. But it appears that, by applying this idea in an absolute manner to the devitrified glasses of RÉAUMUR, a grave error would be committed, which analysis teaches one to avoid. There exist, in fact, two distinct kinds of devitrified or crystallized glasses, resulting from different actions. 1. The first class embraces glasses which, by means of a prolonged heat, and sometimes by the aid of a suitable lute or cement, have arrived at a state of homogeneous combination, and have taken the crystalline form, losing some of their constituent principles. 2. The second kind comprises glasses which, by means of a solidification very slowly effected, are divided into two or more different compounds, some of which have preserved the uncrystallized state, while others have taken a regular crystalline form.

It is possible to discover by analysis what takes place in these two cases. The manner in which RÉAUMUR effected the devitrification has been already stated. In proceeding to examine its results, DUMAS

made the following analysis of a tube of bottle-glass devitrified by M. D'ARCET at the glass-work of La Garre at Paris :—

	Centesimally. Oxygen.	
Silica.....	52.0	= 27.0
Alumina.....	12.0	= 5.6
Sesquioxides of iron and manganese, ..	6.6	= 2.0
Lime.....	27.4	= 7.6
Loss, or potassa,.....	2.0	= 0.2
	100.0	42.4

Comparing this analysis with that of common bottle-glass, already given at page 191, it will be seen that the amount of the potassa is reduced to at least one-third or a half of the ordinary quantity. Moreover, this analysis shows that the sample analysed consisted of one equivalent of sesquisilicate of iron or of alumina, and one equivalent of bisilicate of lime or of potassa.

It is far from probable that the same result would be obtained for all analogous glasses, as regards the state of saturation of the silicates, or their proportion to each other; but it is certain that the potassa almost entirely volatilizes by the devitrification effected in RÉAUMUR's manner, and that the other products arrange themselves, either to constitute a single silicate, or to form several of them, which remain mingled.

D'ARCET found, it is true, that bottle-glass was devitrified without changing its weight. That might happen, in fact, when the oxygen, absorbed by the transition from the oxide of iron to the sesquioxide, is equal in weight to the potassa volatilized.

The chemical changes observed in the devitrification of *bottle-glass* consist, therefore,—1st. In the loss of a part or the whole of the potassa. 2nd. In the passing of a part or the whole of the protoxide of iron and of manganese to the state of sesquioxides. 3rd. In the formation of one or more definite and crystallized silicates, by means of the remaining products.

The second process of devitrification, which consists in the mass being broken up into different chemical compounds, presents itself sometimes alone, but often simultaneously with the preceding. DUMAS mentions

the curious results of an experiment made on the large scale, at the glass-works of Choisy-le-Roi, in which this process was observed to be quite distinct from the preceding. A glass was formed with 100 of sand and 40 of carbonate of soda, perfectly pure and dry. This glass being cooled rapidly, was transparent like ordinary glass. It was re-melted, and submitted to a slow cooling, that the solidification might take place tardily. A glass was thus obtained which was milky, grainy, and evidently devitrified in some places. The devitrified parts were re-melted, and rapidly cooled again after the melting, which furnished common glass once more. This glass, by a new fusion and a prolonged cooling, gave a glass better devitrified than it was the first time. Lastly, the portions which exhibited the most perfect devitrification, being again melted and quickly cooled, again yielded a glass endued with its ordinary characteristics.

This remarkable experiment sufficiently proves that, in the slow solidification of glass, a division of its elements is determined, in consequence of which a definite silicate crystallizes, and thus separates from the remaining mass.

DUMAS states that there existed in the cabinet of the Polytechnic School at Paris, a mass of glass detached from the bottom of a crucible. At the surface of it was an opaque crust, white, crystallized in needles, and of a uniform thickness of one or two lines. All the rest of the mass was of a perfect transparency, but in the interior of it might be observed a multitude of white and opaque prisms, similar to the exterior crust; partly isolated; partly collected in groups of two, three, four, *et cetera*, and forming stars; in some cases more numerous still, and then forming spheroids. The devitrification was therefore effected in this case at the surface, in consequence of the evaporation of the potassa, and in the mass itself, in consequence of the separation which resulted from a slow cooling. Subjoined is the analysis of the two kinds of glass contained in this piece by DUMAS, and that of another specimen by KERSTEN:—

	Kersten.				Dumas.			
	Crystalline portion.		Vitreous portion.		Crystalline portion.		Vitreous portion.	
		Oxygen.		Oxygen.		Oxygen.		Oxygen.
Silicic acid.....	58.8	30.54	60.39	31.40	68.2	35.46	64.7	33.64
Alumina.....	3.3	1.54	6.10	2.84	4.9	2.28	3.5	1.63
Lime,	20.2	5.77	13.40	3.83	12.0	3.43	12.0	3.43
Protoxide of iron,.....	3.5	0.80	3.10	0.70	—	—	—	—
“ manganese,.....	4.2	0.93	2.20	0.49	—	—	—	—
Magnesia,.....	0.5	0.19	0.40	0.15	—	—	—	—
Potassa,.....	2.7	0.45	14.41	3.05	—	—	—	—
Soda,.....	5.5	1.40			1.49	3.81	19.8	5.06

It is evident that, in the specimen analysed by DUMAS, the potassa had been separated from the glass at the instant of crystallization. It is equally manifest that while no simple proportion can be traced between the elements of the transparent glass, one observes, on the contrary, in the crystallized glass a clear and well-defined composition; for the oxygen of the alumina is about one-third of that of the potassa and of the lime, and the oxygen of these three bases is pretty exactly

the fourth of that of the silica. It is, therefore, a compound of one equivalent of quadrisilicate of alumina, and of three equivalents of quadrisilicate of soda or of lime, which corresponds to the composition of ordinary window-glass. More distinctly, in the specimen analysed by DUMAS, the oxygen in the silicic acid is to that of the alumina, and to that of the other bases together, in the following ratios:—

In the crystalline portion, as $35.46 : 2.28 : 7.24 = 18 : 1 : 3$
 In the vitreous matrix, as $33.64 : 1.63 : 8.49 = 15 : 1 : 5$
 For the former, $M_2 O_3, 6 Si O_3 + 9 (M O Si O_3)$
 For the latter, $M_2 O_3, 3 Si O_3 + 15 (M O Si O_3)$

In the specimen analysed by KERSTEN, the relations of the oxygen were as follow:—

In the crystalline portion, as $30.54 : 1.54 : 9.54 = 21 : 1 : 6$
 In the vitreous matrix, as $31.40 : 2.84 : 8.22 = 12 : 1 : 3$
 For the crystalline portion, $M_2 O_3, 3 Si O_3 + 9 (M O Si O_3)$
 For the vitreous matrix, $M_2 O_3, Si O_3 + 18 (M O Si O_3)$

These relations, as deduced from both analyses, render it probable that the two portions were distinct chemical compounds. It may, therefore, be assumed that when the glass is submitted to a slow solidification, there occurs a separation of the least fusible definite compound to which its elements can give rise—the latter then taking the crystalline state.

If the analyses of different glasses previously given had not solved the question, these last two would suffice to demonstrate that all the glasses are silicates in definite proportions, or, at least, mixtures of different definite silicates, dissolved the one by the other. Hence it may be inferred, that by sufficiently prolonging the time of the solidification of a vitreous mass, it would be possible to separate successively compounds more and more fusible, the alkaline base concentrating more and more in the successive residues. And hence, also, may be conceived what takes place in the solidification of lavas, which have so much analogy with the products now under consideration, and an explanation may be given of the formation of natural crystals, so diversified as they appear in their mass.

To sum up—in the words of DUMAS, to whom the Editor is chiefly indebted for what has been stated on this interesting subject—*devitrification is a crystallization of glass, due to the formation of definite compounds infusible at the temperature existing at the instant of the devitrification.* Sometimes this infusibility is produced by the volatilization of the alkaline base; sometimes by a simple division or separation, the alkali then passing into that portion of the glass which preserves the vitreous state. All glasses may therefore be devitrified, for all glasses are capable of passing to the state of definite, and consequently crystallizable, silicates. Glasses which contain at the same time indifferent oxides and basic oxides will devitrify better than others, by the tendency which the indifferent silicates and basic silicates have to combine in definite proportions. Lastly, devitrified glasses will possess very variable properties, for their composition itself will differ completely, according to the nature of the glasses and the circumstances of the devitrification. Thus, sometimes the devitrified glass will be crystallized in needles of considerable size, as happens with window-glass; sometimes it will be crystallized in very fine needles, or even simply transformed into an opaline mass, without appearance of crystals, as in the case of bottle-glass.

Specific Gravity of different kinds of Glass.—It is evident that the specific gravity of glass must depend on its composition. Alkaline calcareous glasses are the lightest; bottle-glass comes next; then plumbiferous

glasses. The following are the results of some experiments:—

	Specific Gravity.
Bohemian glass,.....	2.396
Crown-glass,.....	2.487
Saint Gobain plate-glass,.....	2.488
Cherbourg plate-glass,.....	2.506
Window-glass,.....	2.642
Bottle-glass,.....	2.732
Crystal, or common flint-glass,.....	2.9 to 3.255
Optical flint-glass,.....	3.3 to 3.6

The Editor finds several kinds of glass to give the following specific gravities:—

White flint-glass,.....	3.000
Bottle, common green,.....	2.715
Green-glass, St. Helen's,.....	2.654
Crown-glass,.....	2.520
Leith crystal,.....	3.189
Plate-glass, Ravenhead,.....	2.439

As regards crystal or flint-glass, the density may suffice to give a pretty exact idea of its composition. It is not so with the other kinds of glass, the differences of density of their constituent principles not being sufficiently marked.

LOYSEL attempted to establish formulæ which might permit of passing from the density to the composition, but they are altogether inapplicable. Little, if any, advantage is to be had from them, even for glasses containing lead. These relations vary from so many causes, that, to establish them in a positive manner, it would be necessary to limit oneself to certain glasses, and to deduce them from experiments so delicate and so numerous, that it would be better to have recourse to the ordinary methods of chemical analysis, the results of which will always be more reliable.

CHEMICAL PROPERTIES OF GLASS.—Among the chemical properties of glass, there are some which merit an attentive examination. DUMAS classes them as follows—namely, the effect of the air or of deoxidizing bodies; that of water; that of acids; and that of bases.

Action of Air or Oxygen.—Air or oxygen, cold or hot, provided they are dry, exercise no action on glasses. It is not so with moist air, as will be seen further on, especially with reference to soluble glass. In this case, however, the reagent is water.

Action of Deoxidizing Bodies.—It is evident that deoxidizing bodies may, on the contrary, act with the aid of heat on glasses which contain oxides of iron or of manganese, and especially oxide of lead. In fact, when plumbous glasses are heated with charcoal, or in a current of hydrogen, they very readily undergo a remarkable alteration. The oxide of lead is reduced, and the metal being set free, communicates to the glass a blackish tint. This effect is even so rapid, that one cannot operate on crystal at the enameller's lamp without blackening it greatly, except particular precautions be used. The plan which succeeds best consists in placing a little soap on the wick of the lamp; the flame suddenly assumes a different appearance, and no longer blackens the crystal. It is probable that the presence of the soap affects the capillarity of the wick, and diminishes the ascent of the oil.

Action of Water.—Water does act more or less on all glasses; and there is a great number which it tends to decompose into a soluble alkaline silicate, and

an insoluble earthy and alkaline silicate. It produces in some sort the same separation which would result from a slow cooling, or from the devitrification of the glass. Window glasses, or those which have an analogous composition, are altered in this manner, and very much so, by boiling water. This was long ago remarked by SCHEELÉ. So much is this the case, that water which is boiled for a long time in glass vessels becomes alkaline and turbid by the portion of earthy and insoluble alkaline silicate which forms the residue of its action, and which, detaching itself from the sides of the vessel, remains in suspension in the liquid. This effect is even so marked on crown-glass, plate-glass, and certain window glasses, that it is only necessary to reduce them to a fine powder, and to put them in contact with cold water, in order to impart to the water an alkaline reaction. Lastly, these same glasses have almost always so much of a hygrometrical property, as to become covered with a thin coating of water when they are exposed to the contact of moist air.

This action of water affords an explanation of a considerable number of phenomena occasionally observed on glasses, and chiefly on those with a base of lime and soda, or potassa. Every one knows that looking-glasses sometimes tarnish in the air. This result proceeds from the deposit of a film of hygrometrical water; the same is observed on the glasses of optical instruments. If the glass is well made, the effect proceeds no further; but if it is too alkaline, the deposited water gradually acts upon its surface, and thus produces a decomposition similar to that above-mentioned; in this case the glass is tarnished beyond remedy, or at least it must be repolished. Sometimes the tarnishing is scarcely perceptible, and yet a great alteration may have been produced on the surface. This is observed when one proceeds to heat the glass; its surface becomes detached in very thin lamellar scales, presenting a great regularity of fracture. The glass then remains completely deprived of its polish, wrinkly, and almost opaque. Glass-tubes, globes, retorts, and even measures or standing-glasses, which in laboratories are long exposed to moist air, very often exhibit the same phenomena. In this state the tubes, for example, can no longer be heated at the lamp without losing their polish. Watch-glasses are often observed in the same condition, and even the glasses of optical instruments. It appears, indeed, that glasses which have been polished are more liable to this effect than common glasses. It is well known that glass which has not been polished presents a harder and more brilliant surface, which seems due to the *tempering* it undergoes at the instant of cooling. It is possible, therefore, that polishing renders glasses more readily attacked, by exposing the interior part of the mass, and destroying the hard coat which secured it.

The windows of houses, offices, or public buildings, of an old date, often present a tarnished and unpolished surface, the origin of which must be attributed to a similar cause. When the hygrometrical water has attacked the glass, the slightest changes of temperature cause its surface to splinter, which thus becomes dull, devoid of polish, or at least cracked, and disposed to rise in scales by the least rubbing. This

effect may especially be remarked in the windows of stables; these, after some years, are always so much altered as to exhibit all the phenomena of the decomposition of light produced by thin plates; they become in fact iridescent, and sometimes in a manner very remarkable for the intensity and purity of the colors. This, however, is chiefly due to the ammonia, developed by thecrement and urine of the animals, attacking the silica. On the contrary, it is the weather or moisture which produces the remarkable alteration observed in old glass that is found in ruins or in tombs. Its surface is sometimes entirely decomposed; it has become opaque, and the slightest rubbing causes it to peel off in thin light pellicles, exhibiting all the colors of the rainbow. When the decomposed part is detached from the outer surface of a phial, one would suppose it to be cut; but it is not so: this appearance is due to the interior layer of the decomposed glass, which, by reason of its perfect opacity, reflects all the light which passes through the part still transparent. One finds here, therefore, but only in greater intensity, all the effects which may be so frequently observed on stable windows.

Action of Alkalies.—Since water *per se* is capable of acting on glass with so much energy, it will readily be conceived that *concentrated solutions of potassa and soda* must be capable of attacking it still more powerfully. This kind of reaction has not been much studied. At a red heat, not only potassa and soda, but all the carbonates and all the bases of that class, combine with the elements of glass to constitute glasses more basic. When carbonate is used, the carbonic acid is expelled. It may even be said that all the oxides not decomposable by heat, when heated with glass, combine with it, and thus form glasses transparent or opaque, colored or colorless, more or less readily acted on than the glass employed, according to the proportions. In general, when the proportion of oxide added is much increased, the glass is rendered soluble in acids. This is what is done in the analysis of glass, when it is heated with carbonate of soda, carbonate of baryta, or oxide of lead.

Action of Acids.—The acids, in their turn, should act on glasses with facility. Among these, the hydrofluoric acid must be classed by itself, its action being quite peculiar. The other acids tend to decompose glass, by seizing on the bases and setting the silica free.

Among the bottle-glasses, there are many which resist the action of wine, and which, nevertheless, are powerfully attacked by the nitric, hydrochloric, and sulphuric acids. Salts of lime, of iron, of alumina, and alum, are formed when sulphuric acid is used. This acid produces in the interior of the bottles crystalline nipples or pustules, the base of which ultimately pierces the vessel; these pustules are sometimes of the size of a bean; in all cases the silica set free assumes a jelly-like appearance.

A bottle-glass too rich in alumina is one of those which the acids most readily attack. DUMAS states that he has seen such glasses, which the bitartrate of potassa contained in the wine attacked so quickly that the alteration was perceptible at the end of a few days.

The salt of alumina produced discolors the wine, and imparts to it a disagreeable taste. The bottle becomes corroded, and a flaky deposit is detached from it. At the same time, crystals of different salts are deposited.

Glasses with a lead base are so much the more easily acted on in proportion as they are too rich in lead. Well-made crystal resists acids well. It is the same with window glasses; when too alkaline they are acted on very easily; when well-made, they resist. Moreover, when a glass loses its polish by heat, one may be sure that it is of a nature to be attacked by acids.

Special Action of Hydrofluoric Acid.—It has been stated that the hydrofluoric acid acts on glass in a special manner; and indeed, as this acid transforms the silica into water and fluoride of silicium, it follows that it must act on all glasses. Its action in fact would be always quick and complete, if the formation of a certain quantity of double fluoride of silicium and sodium, of potassium, or calcium, or lead—double fluorides, which are all insoluble, or only slightly soluble—did not diminish the contact, and, consequently, the effect produced.

The hydrofluoric acid, however, attacks glass rapidly when the action is exerted on a small surface, and much acid is employed. This property has been turned to account to etch glass; the acid is employed in a gaseous or liquid state, according to the occasion and the end proposed. The gaseous acid produces opaque traces; the liquid acid transparent ones. But the subject of etching on glass will be alluded to afterwards.

MANUFACTURE OF GLASS.—There are no reliable records of the processes employed by the ancients in the making of glass. But from the time when AGRICOLA described this art, the general arrangement of the furnaces, the mode of fabrication, and the nature of the materials employed, have undergone only modifications of detail, without any change in the general character of the process. No inconsiderable portion of works on the manufacture of glass is usually devoted to the arrangement and construction of the furnaces and pots, the tools employed by the workmen, and the dexterous mechanical operations by which the soft and ductile *metal* is shaped into the various forms that fit it for domestic use and the purposes of science and the arts. These subjects form so important a part of the glass manufacture, that they cannot be entirely omitted in the present work; but the Editor deems it his duty to discuss them as briefly as possible, devoting his principal attention to the chemistry of the manufacture. He will therefore dismiss, in a very few words, the construction of the furnaces, pots, and tools employed.

Glass-house and Furnaces.—The glass-house in which the processes of melting and blowing are performed, is usually built in the form of a truncated cone, open at the top, of sixty or eighty feet in height, and forty or fifty feet in diameter at the base. In the centre of the area is situated the melting furnace, capable of holding from five to ten glass-pots or crucibles for fusing the materials. The grate of the furnace is nearly on a level with the floor of the glass-house; and the ashpit or *cave* is a subterranean passage, extending from each side of the furnace to the exterior of the

building, so as to catch the wind from as many aspects as possible. The particular arrangements of the glass-house, and the construction of the furnaces, are somewhat varied according to the kind of glass prepared.

The plan of a flint-glass-house furnace is shown in the annexed engraving—Fig. 137—where the furnace is represented as containing ten pots, E E. There are as many flues, B B, as pots, one flue being placed between every two pots; and immediately abreast of each pot, and

Fig. 137.

between two flues, is an aperture called the working hole, which is used for introducing the raw materials, and taking out the glass or *metal*. The coals are shovelled through a square hole, D, upon the grate, C C, in the centre of the furnace. The grate bars are supported by two strong iron sleepers, and are protected from the intense heat by being previously covered with a layer of clinkers or potsherds; but, as the furnace attains its maximum heat, sufficient clinkers are formed to serve the purpose. All round the grate-room a bank, A, is raised, termed the *siege*, on which the pots are placed, so that the fire lies, as it were, below the bottom of the pots, and in the centre of the furnace. The sides of the furnace are a little higher than the top of the pots, and the arch or crown is made as low as possible to be consistent with durability.

Fig. 138 is an exterior view of the brick dome, and Fig. 139 an interior sectional elevation of the same,

Fig. 138.

showing the position of the flues, arches, and cave. In Fig. 138, the letters A A indicate the sole of the furnace; B B, the flues; C C, openings or arches, which, after intro-

ducing the pots, are built up, leaving only working holes; **D** is the door for introducing the fuel; and **E** the roof or dome. In Fig. 139, **A** is the cave or air-tunnel below the furnace; **B**, pit of furnace, with grates below;

Fig. 139.

C C, flue or linner holes, through which the flame, not being allowed to issue from the centre, passes up the flues, discharging into the brick dome, and from thence into the funnel and chimney shaft.

The dimensions of a convenient flint-glass melting furnace are given by Mr. APSLEY PELLATT as follows:—A furnace for ten pots of thirty-six inches diameter is twelve feet seven inches in interior diameter, including the flues; the height to the inside of the dome is four and a half feet; each of the arches is three feet one inch by three feet three and a half inches to the highest part. The fire is regulated by the stoker or *teaser*—from the French, *tiseur*—who can raise the heat of the furnace to the highest pitch by opening holes at the bottom of the grate. A ten-pot furnace consumes from eighteen to twenty-four tons of coal per week.

RICHARDSON and RONALDS remark, that the construction of the melting-furnaces in a glass-house is attended with many difficulties, against which it is almost impossible to provide; and the wear and tear becomes a serious item to the manufacturer. The prevailing temperature of a glass furnace, about 20·000° Fahr., presents in itself a serious difficulty; but in cases where open pots are employed, this is materially increased by the volatility of the alkalis, which amounts to nearly twenty-five per cent. of the potassa. The binary compound of silicic acid and alumina becomes changed into a ternary one, through the action of the alkali when clay is employed, and into a silicate of potassa or soda where firestone is substituted; in each case a fusible compound results, which rapidly wastes away, and at last, both pots and furnaces become too much corroded for use. In ordinary cases, three years is the usual duration of these furnaces, except in flint-glass-houses, where they last longer, from the lower melting point of the materials, and the peculiar shape of the pots.

The sides of the furnace are constructed of bricks, formed in moulds made for the purpose. The best fire-clay, mixed with the remains of old pots coarsely ground, is the material employed for making these bricks; but these clays would be much improved for this and many other purposes, by the addition of some coarse sand, or ground pure sandstones. The roof is generally made of sandstone alone, of a coarse grit, and very porous. No cement is employed in the arch, the expansion of the stone, and the partial fusing of the interior surfaces afterwards, bind the whole sufficiently well together.

The crown and plate-glass furnaces are similar to the flint; they are placed also in the middle of the cone, but contain only from four to six pots, each of the capacity of half a ton of metal.

Besides the main or melting furnace, a glass-house contains a variety of furnaces and arches adjoining or around the inside of the cone, for different subsidiary operations. The *calcar arch*, for burning frit, now little used, is a common reverberatory furnace, about ten feet long, seven feet wide, and two in height. In crown-glass works there are also the *blowing furnace*, the *bottoming hole*, and the *flashing furnace*, besides an aperture in the latter termed the *nose-hole*. The uses of these will be explained in connection with the crown-glass manufacture. Lastly, the *leer* or annealing oven is one of the most important appendages of every glass-house. This is the name given to a low arch, open at both ends, in which the manufactured goods are allowed to cool gradually. The arch is usually about sixty feet in length, five feet wide, and not more than from one to two in height. Adjoining the door or receiving end is a small furnace on each side, by which the temperature at that end is maintained just short of a melting heat; but, as there is no other heating power, the arch or oven experiences less and less of the heat as the distance from the mouth is greater,

Fig. 140.

until, at the remote or discharging extremity, the temperature is scarcely higher than that of the atmosphere. There are usually from two to four of these annealing arches placed side by side, as represented in the above engraving, Fig. 140. Along the floor of each is a miniature railway, upon which two rows of iron

trays, called *leer pans*, travel from the hot to the cooler end, where they are taken out. The pans are moved slowly along the leer by means of an endless chain, or sometimes they are gradually pushed forward by the trays last put in. The fuel employed is coke, which imparts the most regular heat for annealing, and is the freest from smoke, the carbon of which, when coal is used, injures the color of the glass. The time required for proper annealing varies from six to sixty hours, the weighty articles requiring the most heat and time. The hotter the goods enter the arch the better, and on this account large articles, before being introduced, receive a final re-heating at the mouth of an empty pot, heated by beechwood, and called the *glory-hole*. Much of the success of annealing depends on the proper direction of the wind, which ought to pass over the fuel of the leer toward the leer chimney at the cooler end, so that the hot air may always radiate in the downward current upon the goods. When an upward or contrary current of wind drives back the heated air from the cool or chimney end toward the fuel at the upper end, where it comes into contact with the hot articles just introduced, great losses from breakage often occur.

Fig. 141.

Kilns, which differ from leers in being closed at the further end, were formerly in general use for annealing goods intended for deep cutting, the kilns, when filled,

being carefully closed up along with the burning fuel. The time required for cooling in this case was usually about a week. To avoid so much delay, the kilns have been superseded by the use of iron covers or a bedding of sand in leers; also by lengthening the leer fire-places, and not filling the pans with glass too quickly.

THE POTS.—The crucibles, or pots, in which the vitreous mixture is melted, require every care to be taken in their preparation. Those used for bottle, crown, and plate-glass have the form of a truncated cone, A—Fig. 141—the narrow end being the base. Their depth is usually four feet six inches; their diameter at top, from four feet to four feet six inches, and at the bottom, about three feet four or six inches. In the same figure are shown the ladle, B, for taking out the glass, and the stirring rod, D. The pots for flint-glass are hooded or covered at the top, and have a mouth, B, in front like a muffle, as shown in Fig. 142; but those for crown, plate, and bottle-glass are open. The horse-shoe-shaped piece of fire-clay, *a*, is inserted in the mouth during the melting, to diminish the aperture.

Fig. 142.

Fine clay is the material of which the glass-pots are made, and it must be as pure and refractory as can be obtained, free from every trace of lime in any state, and sulphide of iron; and the less oxide of iron the better. The kind of slate clay dug out of the coal formation near Stourbridge, which contains very little, if anything, besides silicic acid and alumina, is decidedly preferred to all other compounds found in this country. The clay is mixed with varying proportions of the remains of the old pots, and the *tempering*, or previous preparation of the mixture, requires great attention. A certain quantity of the ground materials, after being mixed with water, is stored away in large wooden bins or receptacles, and turned over from time to time, during which a workman treads it under his naked feet. This *kneading* of the clay renders it very uniform and free from particles of air. The following is the composition of some of the clays employed:—

	Stourbridge. Richardson.			Stourbridge. Editor.		Rhuabon.

Loss,.....	1.20	3.00	—	1.51	1.86	

The proportions given by BARRUEL as most suitable for glass-pots of any description, are thirteen parts of crude aluminous clay, twelve parts of calcined silicious clay, and three parts of the remains of old pots. The last-mentioned material assists the more regular drying of the pots, and renders the whole body more porous, and less liable to crack by heat.

When the mass has been kneaded three times over until it acquires a pasty consistence, it is rolled into small pieces about the size of a sausage, and these wet rolls are placed together upon a wooden or leaden slab, to the thickness of four inches, to form the bottom. It is then turned up at the edges, and built, layer above layer, in successive rings, all formed by the eye of the

workman, without the use of a mould. When the pot has been finished, the sides are made smooth by means of small wooden scrapers.

After the glass pot is formed, it is allowed to remain for a considerable time in an apartment heated by a flue to a little above the ordinary temperature—about 80°—in order that it may be slowly dried in an equal manner throughout its whole thickness. Two or three years is the time allowed by some manufacturers for this gradual desiccation.

Before the pot is set in the furnace, it must be subjected to an annealing process, which consists in gradually increasing its temperature during several days to bright redness. This is usually done in a reverberatory constructed for the purpose, the fire in which must be raised very slowly, not more than a shovelful of coals being introduced at a time, and that at regular intervals. While at a bright red or even a white heat, the pot is quickly transferred, with the assistance of adequate machinery, into its seat in the hot furnace; a part of the face of which must be pulled down, to allow of the ready extraction of the old pot, and introduction of the new one. Before the pot is used, it is *glazed*, as it is technically termed, before being filled with materials; that is, some cullet or old glass is thrown into it, and spread over the sides in a molten state. This penetrates to the depth of a few lines into the substance of the pot, and forms a hard, difficultly fusible enamel, which protects the pot from the further action of the substances added.

The setting of a new pot is a very arduous undertaking, and is generally attended with great excitement, and even danger, on account of the intense heat to which the workmen are exposed. It is generally performed at the end of the week when the work of the glass-house is slackened, and all hands are required to be present to assist at the operation.

A good pot-maker, says Mr. HENRY CHANCE, with two assistants, can furnish three or four pots per week. After a careful drying of many months, they are made ready for the furnace, as has been stated, by a previous heating in a kiln or pot-arch. Here a small lump of coal, thrown against its side, tests the soundness of the pot. If, when struck, it rings well, its future is promising; but if it returns a dull sound, it will probably be short-lived in the furnace, though now and then such a pot will disappoint the bad opinions formed of it, and turn out a respectable pot after all.

The terrible task of setting these pots in the furnace, continues Mr. CHANCE, falls upon the glass-house crew, and the nicety with which these enormous vessels are adjusted in their place, in the teeth of a consuming fire, is, perhaps, that operation which, in the many marvels of glass-making, would most astonish a stranger to such scenes. The average duration of the pots, when thus fixed, is about seven weeks. Some attain the age of ten or twelve; while others, as every manufacturer well knows, terminate their existence prematurely, either from the naturally defective constitution of the pot, or from bad treatment in the pot-arch, or more frequently from its having been *starved*—that is, exposed to a current of cold air in the furnace, through the neglect of the attendant. The breakage of a pot often disturbs

the furnace to such an extent, that the breakage of others frequently follows, and many weeks will sometimes elapse before the disorganization thus produced can be rectified. The loss of the pot and the contained *metal* is nothing as compared with the injury which the glass in the surviving pots, and these pots themselves, are apt to sustain.

CRUDE MATERIALS FOR GLASS-MAKING.—The chemical or theoretical composition of the different varieties of glass has been already given at pages 191 and 192; but as it is quite impossible to obtain or prepare the ingredients in a state of chemical purity previous to fusing them together, it will be necessary to explain the sources from which the materials that go to constitute the different glasses are practically derived for the purposes of the manufacture.

Silica.—It has been stated that all true glasses are practically composed of silica, or silicic acid, in combination with at least two alkaline or earthy bases, and sometimes oxides of lead, zinc, and other metals. Silica, silicic acid, or teroxide of silicium— SiO_2 —is the principal ingredient. It is very abundant in nature, forming a principal constituent in rocks and stones, and existing in a free and almost pure state in flint, agate, chalcedony, rock-crystal, and quartz, the last two being its purest form. Formerly, flint—*silex*—calcined and ground, was used as the source of the silica, and hence the name of *flint-glass*. Sand, however, is now employed as the most general and economical source of silica, and renders the process of grinding unnecessary. At the same time the great variations in the purity of this material render requisite a careful selection for the different kinds of glass, and the manufacturer must choose such as the microscope and analysis show to be most suitable for his purpose. The finest English sands are from Alum Bay in the Isle of Wight, and Lynn on the coast of Norfolk. The French obtain a very superior sand from the forest of Fontainebleau, in the neighborhood of Paris; and Mr. H. CHANCE justly remarks, that to the purity of this and their other materials the superior color of their glass may be partly ascribed.

The sand, being always more or less impure when brought to the glass-works, is conveyed to an upper room, and thrown into a trough of water, where it is carefully washed. It is then placed in a trough over an oven, and, when partially dried, passes through holes into the oven. When quite dry, it leaves the oven in the state of fine, glittering white particles, like powdered quartz. These precautions are not necessary for bottle-glass.

Potassa and Soda.—The alkalies used in the manufacture of common colored glass, such as those used for green bottles, are obtained, as far as the potassa is concerned, from common *ashes*, and the soda from the *ashes of sea-plants*, or refuse soda. Better kinds of glass are made with crude potassa and soda-ash, and the best from purified potassa and soda-ash. Not more than thirty years have elapsed since crown and sheet glass were manufactured from the crude alkali obtained from kelp, the preparation of which for this purpose employed a large population on the Northern shores of Scotland and West of Ireland, and the abandonment of this material, when the duty was taken off barilla,

plunged whole districts into idleness and misery. The kelp was used simply in combination with sand—the kelp containing soda and potassa, and furnishing the necessary amount of lime; but the glass thus produced was of very variable, and often most inferior quality. The discovery of LE BLANC in 1792, which effected the conversion of common salt into carbonate of soda, was the commencement of a new era in the history of Continental flint-glass; but the introduction of carbonate of soda, prepared from salt, into the glass manufacture of England, dates only from the year 1831. Ultimately sulphate of soda was substituted, except for plate-glass, the manufacturers of which still adhere to the carbonate. The black bottles of Newcastle are made from common rock-salt, and sand from the bed of the river, with the carbonate of lime of the soap-works, and the tank waste of the alkali makers; but for all better kinds of glass the circuitous combination of silica and alkali is still found necessary. The carbonate of potassa is obtained chiefly from Canada and the United States, and requires a process of washing previous to use. The state to which it is brought by the process of cleansing is that of fine white grains, differing but little, to an unpractised eye, from the prepared sand.

Lime.—This substance, which forms an important constituent in flint-glass, may be introduced either as a carbonate, or slaked or burned. Limestone, however, that contains proto-carbonate of iron, must be excluded from the mixture for making white glass. The action of lime is to render the alkaline silicates insoluble, and when rightly balanced by the other ingredients, it promotes the fusion of the whole, and improves the quality, but when added in excess, the glass becomes hard and difficult to work, and subject to devitrification.

Lead.—The next substance in point of importance is lead, which forms the distinguishing ingredient in crystal or common flint-glass, optical glass, and strass. These glasses are fused from a mixture containing litharge— Pb O —or minium—red lead, $\text{Pb}_3 \text{O}_4$. Of these two compounds, the latter is preferred on account of its finer state of division, its pulverulent form, and because it is decomposed in the glass-pot into ordinary protoxide of lead and oxygen, which latter oxidizes, and removes many impurities, as, for example, charcoal. An excess of lead acts injuriously upon the melting vessels, and, besides inducing too great softness in the glass, gives it a yellow tinge.

Baryta.—This substance, in the form known as *heavy spar*— Ba O , S O_3 —is sometimes added to the constituents of common bottle-glass, to render it more easy of fusion.

Alumina.—The sesquioxide of aluminum— $\text{Al}_2 \text{O}_3$ —though seldom purposely introduced into glass, is always accidentally present, brought there by the action of the materials upon the clay of the pots in which they are melted. Alumina, if present in any quantity, is always an undesirable ingredient, as, by increasing the number of silicates, it renders the glass more liable to devitrification, it being well known that the more compound a glass is, the more does it display this tendency. Hence, bottle-glass, which contains a greater variety of bases than any other, is of all the most easily devitrified.

Iron.—Another unwelcome element is iron, which is

almost always present in the sand, in the sulphate of soda, when employed, and in the chalk, partly in the state of protoxide, the coloring effect of which is partially destroyed by other ingredients, to be afterwards mentioned.

Arsenic.—A little arsenic promotes the decomposition of the other ingredients, and tends to dissipate carbonaceous impurities not otherwise disposed of; but, in excess, it produces a milkiness in the glass, which time will increase.

Cullet.—Another substance is added—abundantly produced in every manufactory of glass—namely, a quantity of waste glass, or cullet, which, being more fusible than the raw materials, facilitates the melting. For this purpose, the waste glass in the glass-house, and that collected in the neighborhood, are carefully sorted, cleaned, ground, and incorporated with the mixture *for similar kinds of glass*. Great care must, however, be taken that no broken glass of an inferior kind is mixed with the ingredients for finer glass. The cullet not only incites fusion, but materially aids the union of the bases with the silicic acid.

Decoloring Materials.—It has been stated in the historical notice that every description of glass exhibits a tendency to color, which probably led to the idea of stained glass. This tendency is more or less developed, even when proper proportions and the purest materials for the mixture have been employed; and as any tinge is considered a defect in white glass, or that which is employed for windows and particularly in the finer kinds of glass, certain materials are employed with the special object of counteracting it. To this class of substances belong *binocide of manganese*, *arsenic*, already mentioned, and *nitrate of potassa*. The accidental elements which usually color the glass are *iron* and *carbon*, or carbonaceous matters, and in all cases the substances above-mentioned are employed to neutralize or counteract these by means of *oxidation*.

For example, if particles of carbon or soot from the fire or flame become mixed and surrounded with the melted glass, these, by their exclusion from the access of air, are prevented burning, and a brown or nearly black color is produced, which is removed by the conversion of the carbon into carbonic oxide through the influence of the oxidizing or decoloring material. The manner in which manganese acts on the protoxide of iron has been already explained—page 189—and is similar to its action on carbonaceous matters, which are thus removed in a gaseous form from the melted mass. A few ounces of the binocide of manganese are, therefore, usually added to the materials for making flint-glass, which is always required in a state of great purity; and, from the cleansing action of this material, it has received the familiar title of *glass-makers' soap*. It must, however, be used sparingly; for an excess of it produces a compound of silicic acid with sesquioxide of manganese, which communicates a lilac or amethystine color to the glass. The approved remedy for this, when the error has been committed, is to stir up the colored mass with a wooden pole, which reduces the sesquioxide to the protoxide, and the lilac color disappears.

Some manufacturers use manganese, on account of the reddish tinge it imparts to glass, expressly to disguise the bad green or yellow color produced by the other materials. In this case two tinged glasses are formed, which mask each other's defects, the green and red rays combining together, as supplementary colors, to transmit white light. Indeed, in plate-glass for fine windows, a slight excess of manganese is sometimes allowed, expressly to produce a delicate amethystine tint, which improves the complexion of persons who receive the light of day through the window.

Smalt, a blue glass, is sometimes used, like manganese, to mask the bad color produced by the other materials. Properly speaking, however, the decoloring agents are those which act by oxidizing the carbon or the protoxide of iron, and thereby actually expelling the lime. In this way nitrate of potassa reacts before the glass enters into perfect fusion; arsenious acid, arsenic acid, and their salts, exert their action at a temperature above the fusing point, and are volatilized.

Glass from Felspar.—The making of glass by means of felspar is an idea which naturally suggests itself to the mind, when one considers the ready vitrification of this mineral, and was suggested even long ago by M. GHÉRARD in the memoirs of the Academy of Berlin. According to this authority, the following mixture is proper for a window-glass, namely, two parts felspar, two parts sand, one part chalk, which would give, for the composition of the glass, supposing no volatilization of the potassa during the melting, nearly the following:—

	Centesimally.
Silica,	73
Alumina,	8
Potassa,	7
Lime,	12
	100

These ill-calculated proportions could only give a glass difficult to melt, and prone to devitrify. This, says DUMAS, is exactly what happened in an experiment made on the large scale by M. REY, under the eyes of CHAPTAL and ALLUT. The melting required a twice longer time than the usual, but it furnished a beautiful glass. The experiment was supposed to be a fortunate one; but when the crucible was cooled sufficiently to admit of the working of the mass, it was found quite opaque, milky, and clotty—in fact, devitrified. Must felspar, therefore, be renounced? It is difficult to admit this. If a mixture be made of one hundred parts of felspar, one hundred parts of Arcueil clay, or some analogous clay, and eighty of quicklime, or its equivalent in chalk, a glass of the following composition will be produced:—

	Felspar.	Clay.	Glass.	Or centesimally.
Silica,	66	63	129	46·3
Alumina,	18	37	55	20·0
Potassa,	16	—	16	5·7
Lime,	—	—	80	28·0
			280	100·0

—that is to say, a glass which, if the clay is free from iron, would be quite of the same nature and color as bottle-glass, and which would present advantages as well as disadvantages. As regards common window-

glass, or analogous glasses, felspar should be capable of entering into these in the proportion of one-third or one-fourth, without serious disadvantage. A glass would be produced which would differ from common glass only by the presence of four hundredths of alumina, and glasses are met with in commerce which contain this quantity and even more. Lastly, it is probable that by suitable additions of borax, boracic acid, or oxide of lead, one might get felspar itself to produce a glass endued with all the desirable qualities.

Glass from Volcanic Products.—DUMAS remarks that certain lavas, pumices, pitchstone, and other volcanic products, approach so closely to bottle-glass in their composition, that the possibility of turning them to account in this way cannot be doubted. The merit of the first attempts of this kind is due to CHAPTAL; and if these attempts did not succeed, this must be attributed to the time at which they were made, rather than to the idea itself, which is both good in theory and must be capable of succeeding in practice. The analyses will be sufficient to prove this:—

	Lipari pumice.	Basalt of Haseburg.	Basalt of Staffa.	Pitchstone of Mismal.
Silica,	77·5	44·5	48·0	73·0
Alumina,	17·5	16·7	16·0	14·5
Oxide of iron,	1·7	20·0	16·0	1·0
Soda, }	3·0	2·6	4·0	1·75
Potassa, }				
Lime,	—	9·5	9·0	1·0
Magnesia,	—	2·2	—	—
Water,	—	2·0	5·0	8·5
Hydrochloric acid,	—	—	1·0	·25
Loss,	·30	2·5	1·0	·25
	100·0	100·0	100·0	100·0

With pumice-stone, forge-scoriæ, chalk, and a little soda in proper proportions, bottle-glass might therefore be made. Basalt would require only the addition of a little chalk and soda. Pitchstone treated like pumice-stone would furnish it also.

The trials made by the directions of CHAPTAL succeeded so far as the matter examined by him was employed; but when another volcanic product came to be used, the results were bad, the proportions being deranged. A very simple analysis would have prevented all trouble, and would have preserved their proper rank to these volcanic matters, the excellent effects of which have been demonstrated by a sufficiently long experience.

It was in 1780 that CHAPTAL, then Professor of Chemistry at Montpellier, proposed the use of lava. M. DUCROS, a glassmaker in the environs of Alais, melted, with coal, the lava of the extinct volcano of Montferrier, without any addition, and made some bottles of it. M. de CASTLEVIEL, another glassmaker of the country, melted, with wood fuel, a mixture of sand, lava, and soda, and thus produced bottles lighter and stronger than those usually manufactured. These bottles had such great success that the demand could not be supplied. But at the expiration of four years, the bottles which were produced no longer resembled the first ones: they were much inferior; the manufactory lost its reputation, and was compelled to abandon the system which it had just tried with so much success.

The nature of the lava, therefore, had changed, and

the same proportions being no longer suitable, an analysis alone could have guided the operator. It is with this that the process must be commenced, if it is intended to resume a manufacture, worthy, in so many respects, of being submitted to trials which the state of science would now render much easier. It was in consequence of taking a different course that M. de CASTLEVIEL failed, and that M. FOUGEROUX de BONDAROX, who appears to have been occupied in 1787 with the same subject, without any knowledge of the preceding facts, succeeded no better.

THE FUEL.—The fuel formerly employed in England in the making of glass was exclusively *coal*, but of late it has been found that, in London especially, many advantages result from using *oven-burned coke*, which produces less smoke and soot, and is, therefore, much better adapted for the finer glasses. Some glass-houses have all the requisite accommodation for making coke. In France both coal and coke are employed, and sometimes *wood*; but BARRUEL states that wood has been generally abandoned as being more costly, and producing less heat than coal, so that with the former the fusing and refining of the metal require longer time. In Germany *wood* is generally employed, and in some few places *peat*. Even the best air-dried wood would fall far short of producing the desired effect, in consequence of the amount of water which it still retains, and therefore it has been the practice on the Continent, from a very ancient period, to bake the air-dried wood in a particular kind of furnace until it begins to become brown, or until the whole of its water has been volatilized. Peat when used in the glass-house must be perfectly dry, and afford only a small amount of ash.

PREPARATION OF THE MATERIALS.—A great saving of time and fuel is effected by carefully grinding and intimately mixing the materials previous to the melting. For this purpose edge-stones and coarse sieves are essential in a glass-house. Until quite recently, the mixing and sifting were always performed by hand, and the operation was therefore imperfectly performed, the mixture so produced being little calculated to favor those chemical changes and mutual reactions of the materials which are necessary to the formation of a

Fig. 143.

homogeneous fluid transparent body. To obviate this disadvantage, a mixing apparatus, especially intended for crown-glass, has lately been contrived by Mr. CHANCE. This very simple machine, which is shown

partly in section in Fig. 143, is made entirely of wood, and consists of a semi-cylindrical chamber, with an opening, A, at the top, for introducing the materials, and another in the semicircular bottom at D, through which they are removed; B is a cylinder in which a number of oblique beaters are fixed, and the whole is made to revolve by a handle or by a shaft from the steam-engine connected with the axis, C. Mr. COOPER applied with the best effect a simple revolving wooden barrel, similar to those employed in the powder factories. The composition, when mixed, is termed *batch* or *frit*—the latter word being derived from the circumstance, that during the period when barilla, kelp, and other forms of crude alkali were in use, it was the custom to subject the materials to the preliminary operation of *fritting* or stirring them together under the heat of a reverberatory furnace, thereby effecting partial decomposition, and burning off any carbonaceous impurities; but the introduction of alkali prepared from common salt has, in most cases, removed the necessity of this treatment. One great advantage of fritting consisted in the partial union which it effected between the silicic acid and the bases, so that the latter were not volatilized in the furnace previous to the formation of the glass, and the pots and sides of the furnace were consequently less exposed to the injurious action of their vapors. With the purer materials now employed in the manufacture, the advantages gained by the operation are not generally considered sufficient to compensate for the loss of fuel incurred in producing the high degree of heat required to perform it.

MELTING.—The raw materials, consisting essentially of sand or silica as the base, and alkali as the flux or solvent, having been thoroughly incorporated with a suitable proportion of cullet or broken glass of the same kind, are introduced by means of a clean iron shovel into the melting-pot, which has been previously raised to a white heat. But the whole of the mixture is not introduced at once, for the mass of glass which a pot will hold occupies before fusion, in the state of frit, just twice the space of the melted glass. Not more than one-third of the mixture is therefore introduced at first through the working holes, the temperature is then raised to the maximum, and as the mass subsides by melting, a fresh quantity is introduced, until the pot is filled with melted glass. During the whole period of the melting or *found*, the stokers or *teazers* keep the furnace well supplied with fuel, so as to prevent any portion of the grates becoming uncovered, in which case a rush of cold air from below might split some of the pots. At the same time the *founders*—from the French, *fondeurs*—are engaged in noting the progress of the fusion, by taking from time to time proofs or drops from the pots, by means of a short rod, flattened at one end, and examining if any undissolved grains of sand are perceptible on refrigeration, and whether the mass, which still contains a quantity of air-bubbles, appears uniform throughout. So long as carbonic acid is evolved in abundance, or during the *boil*, the mass is agitated by the escape of the larger bubbles of gas in a manner most favorable to the operation, this motion answers the

purpose of stirring, and mixes the compounds of variable degrees of fusibility and density, which are at first produced, with each other; at a later period, when the disengagement of gas ceases, the denser compounds are apt to settle down at the bottom of the pot, where the temperature is about one-fourth lower, and is, consequently, incapable of preventing the deposition by the production of ascending currents. This evil is moderated on the Continent by stirring with the scooping ladle, or by thrusting a piece of arsenious acid to the bottom of the pot, and thus causing a forcible expulsion of vapor from that part of the vessel. At the close of the melting process, the contents of the pot are not by any means pure, or equally mixed. All the solid matter is dissolved, but the mass of glass is full of small vesicles of gas, presents a spongy rather than a dense appearance, and is not yet in a state fit for working. The surface is also covered by a layer of so-called *glass-gall* or *sandiver*, a melted mixture of salts, which have not been volatilized, nor combined with silica during the process of melting, and consisting chiefly of chloride of potassium—or sodium—and sulphates, which in consequence of imperfect vitrification have escaped decomposition.—*Knapp*.

The following, says RICHARDSON and RONALDS, has been found to be the composition of this saline matter, glass-gall or sandiver, which is skimmed off the surface of the melting materials, and is technically termed *salts*:—

Constituents.	German plate-glass.	Crystal- glass.	Bottle- glass.
Water,	1·65	·10	1·00
Sulphate of soda,	83·32	90·51	55·92
Sulphate of lime,	10·35	6·00	25·11
Chloride of sodium,	1·43	·04	·20
Carbonate of soda,	trace	—	—
Potassa,	—	—	trace
Insoluble matter,	3·25	3·35	17·77
	100·00	100·00	100·00

Glass-gall, when occurring in large quantity, is removed with ladles, and is employed on the Continent by saltpetre and alum manufacturers, or workers in bronze; in the varieties of glass prepared from purer or purified materials, where, instead of crude potassa, ashes, or soda, purified substances have been employed, either no glass-gall is produced, or that which appears is easily removed by volatilization.

FINING.—For some time the glass does not become transparent, the opacity being due to bubbles of air or gas, and to the lime and earthy impurities which do not fuse. The object of the *fining*, which is the last process in glass-making, properly so called, is the removal of these by the subsidence of the heavier particles to the bottom and the escape of gas at the surface. For this purpose the glass must be brought to the most fluid state possible, and the heat is therefore raised and sustained for some hours at the highest point. In Germany this part of the process is termed *heiss-schüren*, or *hot-covering*. In forty or forty-eight hours after charging, the vitrification is complete. When all the gas-bubbles have passed off, and the sandiver has become transparent and colorless, the temperature of the pot is lowered by diminishing the draught—a process termed *kalt-schüren*, or *cold-covering*—the object of which is to

bring the glass from a state of nearly perfect fluidity, in which it could not be worked, to that free viscid or plastic condition necessary for the working. For this purpose the bars of the furnace are plastered up. The great thickness of the walls, and the slow combustion of the fuel, which is supplied in moderate quantity, keep the furnace hot enough to retain the glass in a workable viscid state during the period in which the glass is blown or otherwise shaped into the required forms.

The reactions which take place in the pot or crucible are very easy to understand. For example, if the silica has been mixed with carbonate of soda and carbonate of lime, the silica, at a high temperature, seizes on the soda and lime, and the carbonic acid is disengaged. In the same manner, if silica has been mixed with carbonate of potassa and minium, this last returns to the state of massicot, and the silica then combines with it and the potassa. There is, therefore, in this case, first a disengagement of oxygen, then an elimination of carbonic acid.

These evolutions of gas which constantly accompany the production of glass, explain the presence of the *air bubbles* already mentioned as so frequently observed in the vitreous mass. To expel these, it has been stated that the temperature must be raised very high, that the glass may become quite fluid. But as the potassa and soda may be volatilized at this high degree of heat, one is obliged to introduce into the compositions much more potassa and soda than the glass is intended to retain.

This elevated temperature is also necessary in all cases where impure alkalis are used. The presence of the chlorides, and even that of the sulphates which melt without mixing with the glass, would occasion in the latter a multitude of white and opaque nodules disseminated through its mass. At a high heat both of these matters, being lighter than the glass, rise and float on the surface, constituting the principal portions of the glass-gall or sandiver above alluded to. It must be stated, however, that ever since the salts of soda have been sold at a low price, and are consequently generally used, very little glass-gall has been produced in the manufacture of the ordinary kinds of white glass; but in bottle-works this impurity always occurs, because crude sodas are employed.

FAULTS IN THE GLASS.—Notwithstanding all the precautions that may be taken, air-bubbles frequently remain, and generally exist in great number when the fining process has been obstructed by too great difficulty of fusion in the glass. They are technically termed *seed*, *blibe*, or *blister*.

Two further accidents to which the glass is liable are known as *threads* or *strings*, which are generally contracted during the blowing, when cold particles of glass drop into the viscid or imperfectly melted metal, and not having time to undergo fusion remain hard, and appear as unsightly projections from the blown vessels.

Waves and *striae* are faults of too common occurrence, arising from a want of homogeneity in the vitreous mass. The latter of these terms is applied to the effect produced when the density of the glass, in consequence of imperfect fusion, is not uniform throughout,

and all the parts, though equal in transparency, do not refract the light equally; and consequently, images of objects seen through the glass appear out of place or distorted. This fault is very objectionable in plate-glass for mirrors or windows, as well as in crystal or flint-glass for optical purposes. *Waves* are superficial and protuberant striæ, which always occur when the glass is blown too cold.

A not less serious evil, which is frequently a source of color in the glass, arises from the action of the alkaline vapors upon the constituents of the sides or roof of the furnace, particularly when chloride of sodium or sulphate of soda is used in the manufacture. The volatilization of the alkali, whether soda or potassa, produces over the pots a rapid vitrification of the bricks of the vault, and hence drops of *colored glass*, known by the name of *tears*, which occasionally fall into the pots. These are produced by the silicic acid of the bricks combining with the alkali, and forming with it, and with the iron and alumina of the clay, a green and very infusible glass, which sinks to the bottom of the pot from its greater density, leaving in its course a fibrous tail which remains in the glass. Imperfections of the same kind are produced, though less frequently, by the action of the glass upon the walls of the pot itself.

According to KIRN, the drops of aluminous glass may be prevented from falling into the pots by constructing the latter and the arch of the furnace in the manner represented in Fig. 144. In this case the portion of the wall of the furnace, which comprises the working hole, B, is made so large that drops, falling perpendicularly from any protuberance or irregularity, b, can only reach the

Fig. 144.

exterior of the inflected margin, a, of the pot, A; and the size of the working hole is reduced to the proper dimensions by a second less solid arch, D. Another plan, mentioned by KNAPP, is to make the working hole in the perpendicular wall of the furnace, and to spring the arch of such a form that the angle of the part over the pot may be sufficient to cause the *tears* to flow down the arch instead of dropping into the pot.

WORKING TOOLS AND APPARATUS.—The tools represented by BLANCOURT, in his work *On the Art of Glass*, which was printed at London in 1699, are almost precisely the same as those now in use; and the author's account of their mode of working might almost be taken as a description of the modern process. To those

curious on the subject, BLANCOURT's description is well worthy of perusal.

The most important of these instruments is the *pipe*, on the end of which the glass is taken up by the workman, and blown into spheres or bulbs, to be subsequently shaped into different forms, as will be afterwards described. A section of this indispensable instrument is shown in Fig. 145. It is simply a tube,

Fig. 145.

composed of wrought-iron, four to five feet long, one inch thick, and about one quarter to one inch in the bore. It is provided with a knob at each end, the one of which, a, serves as a mouth-piece, whilst to the other, b, the melted glass is attached. The upper portion is surrounded by a wooden cover, c, to protect the hands of the workman from the heat of the metal. A companion to this instrument is a solid iron rod, known as the *pontil* or *ponty*, which serves to receive the glass after it is blown on the pipe. The *spring-tool*, A—Fig. 146

Fig. 146.

—is a species of tongs for laying hold of half-formed handles, and for seizing the glass while making. The *pucellas*, B, have prongs resembling the cutting part of shears, but blunt, and are used for rubbing the outside of solid or hollow glass, and pressing it into smaller diameter, at the same time elongating the parts by rotation. The battledore, c, is made of wood, and is used for flattening the glass when necessary. The shears, D, are strong scissors for cutting and shaping the edges and handles of glass vessels while in a soft state. The fork, E, is employed for carrying the finished articles to the annealing oven.

An important part of the glass-blower's furniture is the *marver*, which consists of an iron plate or slab, resting on a stone or on wooden supports, and having a polished surface, on which the mass of glass that has been gathered at the end of the blowing tube is rolled, to give it a symmetrical form. The term *marver* is derived from the French *marbre*, a marble slab being formerly used. The *glass-maker's chair*—Fig. 147—is a flat seat of wood, about ten inches wide, each end of which is fixed to a frame connected with four legs and two

inclined arms, upon which is screwed an edging of wrought-iron for rolling the blowing tube with the hot

Fig. 147.

glass backwards and forwards with the left hand, while the required form is given to the glass with the pucellas held in the right.

Continual rotation of the melted mass is the principal point to be attended to in most of the glass-blower's operations; but these will be best described in connection with the special manufacture of the different varieties of glass.

SPECIAL MANUFACTURE.—A visit to the glass-house will convey a much more vivid idea of the beautiful art of the glass-blower, and the wonderful material with which he works, than the most elaborate written description or pictorial illustrations. There is, moreover, so much of the *mechanical* connected with the fabrication of glass, that great part of it does not properly fall within the scope of this work. In proceeding, therefore, to describe the details of the different departments of the manufacture, the Editor will dwell as briefly as possible on those operations which do not involve the application of chemical agencies.

The arrangement to be followed will be somewhat similar to that already indicated, as adopted by KNAPP, but with some important modifications—beginning with the coarser or commoner qualities, and rising by a natural gradation to the finer and rarer kinds of glass manufactured for optical lenses or ornamental purposes. On this principle, the following arrangement will embrace all that is necessary:—I. ORDINARY or GREEN BOTTLE-GLASS. II. WHITE BOTTLE-GLASS, including *refractory Bohemian and Foreign crown*. III. WINDOW-GLASS, embracing—1. *English crown*, and 2. *Sheet or cylinder glass*. IV. PLATE-GLASS, with the process of silvering mirrors. V. CRYSTAL or COMMON FLINT-GLASS, and OPTICAL FLINT-GLASS. VI. STRASS and COLORED or STAINED GLASS. VII. SOLUBLE GLASS.

I. GREEN BOTTLE-GLASS.—The materials for common glass bottles are coarser and cheaper than for any other kinds of glass; and, in consequence of this very coarseness or want of refining, the elements which enter its composition are more numerous, consisting, as already stated, of silica, lime, potassa or soda, oxides of iron and manganese. These last oxides communi-

cate a color to this glass, which owes, at the same time, a part of its characteristic hue to the charcoal. Indeed, as the color of bottle-glass may be considered as essential to it, or at least does not injure its sale or diminish its value for the purposes to which it is applied, no decoloring materials are used, and it is melted in open pots, even when coal is used as the fuel, which is always the case in this country. The omission of decoloring materials forms the distinguishing feature in the manufacture of ordinary bottle-glass.

Materials.—The English laws, till lately, prohibited the use of fine materials for making ordinary bottles. Nothing but the common river sand and soap-boilers' waste was allowed. About three parts of waste, consisting of the insoluble residuum of kelp, mixed with lime and a little saline substance, were used for one part of sand. This waste was first of all calcined in two of the fire arches or reverberatories reserved for that purpose, called the coarse arches, where it was kept at a red heat, with occasional stirring, from twenty-four to thirty hours, being the period of a journey or *journée*—a day—in which the materials could be melted and worked into bottles. The roasted soap-waste was then withdrawn, under the name of ashes, from its arch, coarsely ground, and mixed with its proper proportion of sand. This mixture was now put into the fine arch, and calcined during the working journey, which extended to ten or twelve hours. Whenever the pots were worked out, that frit was immediately transferred into them in its ignited state; and the founding process proceeded with such despatch, that this first charge was completely melted down in six hours, so that the pots might admit to be filled up again with the second charge of frit, which was founded in four hours more. The heat was briskly continued, and in the course of from twelve to eighteen hours, according to the size of the pots, the quality of the fuel, and the draught of the furnace, the vitrification was complete.

At the present time, in choosing ingredients for bottle-glass, economy is the chief object; color and appearance are here of no moment. Little soda or potassa is admitted into the composition of this description of glass; and, as the carbonates of these bases are costly, it is usual to employ in the bottle glass-works only recent ashes or wrack-soda to furnish the alkali. Moreover, the other materials are taken in a state of impurity fit only for bottles.

The primary materials of the manufacture of this kind of glass are yellow and ferruginous sands, residues proceeding from the lies of the soap and soda works, lixiviated ashes, common ashes, wrack sodas, and clay.

The colored sands are even preferable to white sands for bottle-glass, the oxide of iron, which colors them, performing the part of a flux. They do not require any washing or other preparation; nevertheless, any coarse foreign substances, such as pyrites, flints, *et cetera*, are separated from them. For this purpose they are dried, and passed through a sieve. The clay best adapted for bottle-glass is a yellow marly earth; it is furnace-clay, containing, therefore, alumina, silica, carbonate of lime, oxides of iron and manganese; it has not much of a binding quality, and is easily reduced to powder when dry, which facilitates the mixtures.

The ashes are generally obtained from common

domestic fires. Those are preferred on the Continent which proceed from the combustion of new wood or charcoal. They are sifted and dried before using. The wrack-soda is employed in a powdered state; it is even passed through a very close wire sieve.

The following is given by DUMAS as the usual proportion of these materials:—For

ORDINARY FRENCH BOTTLE-GLASS.

30-40 pounds.....	varec.
160-170 "	lixivated ashes.
30-40 "	fresh ashes.
80-100 "	clay containing iron.
100 "	broken glass.

The proportions in English bottle-glass are slightly different:—

ENGLISH BOTTLE-GLASS.

100 pounds.....	lixivated ashes.
40-90 "	kelp.
30-40 "	wood-ashes.
80-100 "	clay.
100 "	cullet.

The amount of cullet is not particular; it is increased for the first and second melting, when new pots are used. If a very argillaceous sand is employed, it is necessary to suppress the clay, and supply lime by a suitable addition of chalk. Natron or crude soda may be used to replace the potassa yielded by the varec; but in this case care is taken to add to the mixture a certain quantity of fresh ashes, that the glass may not be wanting in potassa.

The proportions given in the preceding recipes, as well as in those that follow, are calculated for one hundred pounds of sand:—

FOR CHAMPAGNE BOTTLES, ACCORDING TO JAHKEL.

200 pounds.....	felspar.
20 "	lime.
15 "	common salt.
125 "	iron slag.

ORDINARY GREEN BOTTLE-GLASS.

72 pounds.....	lime.
280-278 "	lixivated wood-ashes.

DARK GREEN BOTTLE-GLASS.

20 pounds.....	dry Glauber's salt.
18 "	soap-boilers' flux.
1 "	Scheffel—Pruss.—lixivated ash.
39 "	glass from the hearth.
179 "	green cullet or broken glass.
45 "	basalt.

Melting.—The melting-furnace for bottle-glass commonly contains only six pots. These are about three feet in height, and nearly the same in diameter. They are filled almost to the edges; and when the matter has sunk down, and is converted into a glass, more of the composition is put into the pots, and the fire is urged. The meltings are rapid; for as most of the bottle-glass compositions furnish but little glass-gall, no time is lost in fining. The process lasts from seven to eight hours, and, when it is concluded, the fire is slackened, that the glass may thicken to the point suitable for working it. For this purpose the fire-place is heaped up with small coal, draughts are intercepted as much as possible, and care is taken not to touch the fire during the working of the glass, lest the combustion should be re-excited.

Mechanical Operations.—The working or shaping of bottle-glass is very simple in principle, and yet the operations involved are somewhat complex in detail. These may be summarily stated as follows:—The assistant collects or *gathers* on the end of the pipe—Fig. 145—the requisite body of glass, and passes it to the blower. The latter, by blowing and constantly turning the pipe, gradually forms the body of the bottle, which is finished in a mould. While the bottle is in the mould, the workman continues to blow and to turn. He then raises the pipe, and, holding the bottle in a vertical and reversed position, he depresses or hollows the bottom. The bottle is then cut at the neck, and the iron rod termed the ponty fixed at the opposite end of it; the edge of the neck is rounded, and the ring or cord which encircles it is put on, as also the seal, if the bottle is intended to have one. The ponty then passes into the hands of the assistant, whose duty it is to carry it to the annealing furnace. He there detaches it from the rod by a slight blow.

Such are the chief operations of the process of bottle-making, as described by DUMAS; but as this manufacture affords a good instance of the dexterous manipulations which are practised in blowing glass, a subject deeply interesting to the practical chemist, the following more detailed account, which is given by KNAPP as descriptive of the mode of working carried on in Spessart, will be not unacceptable to the reader:—

As soon as the working holes are opened, and the surface of the glass is cleared from sandiver or glass-gall, the workman attaches as much melted glass to the end of the pipe as he considers necessary for the production of a single bottle; his eye and hand are here unflinching guides as to the requisite quantity. By dipping the previously warmed pipe into the pot, a little glass remains attached to the end; after turning this in the air before the hole until it is cooled, and blowing slightly into it to render it hollow, a fresh layer of glass may be attached to it in the pot; to this, a third is added in the same manner, until the ball at the end of the pipe has accumulated to a sufficient size, *a*—Fig. 148. That this ball may become uniformly tractable in the subsequent forming, it is held by the workman in the flame of the furnace through the working hole; it is then brought into one of the round concavities of the *marver*, *b*, which is wetted or moistened when used. Here the ball gradually assumes the form of a thick hollow globe, or rather pear-shaped vessel. It acquires this shape by the constant rotary motion given by the workman to the pipe, whilst the cooling and stiffening of the mass is rendered uniform by the marver, and is prevented shrinking together by constantly blowing into the tube with very little force. The mass of *metal*, which, as already stated, is the technical term applied to glass during working, must be equally distributed round the axis of the instrument, and advanced in front of its mouth, being connected with it only by a short neck. Towards the front part, where the subsequent widening occurs, and the mass is blown out, it is thickest; the portion nearest the pipe is less massive.

Thus far advanced, the glass has again become cool, and is re-heated by insertion into the working hole, in such a manner that the front part receives the chief

portion of the heat, and becomes the softer. The pear-shaped vessel is now lengthened by the blower, and its form is made somewhat to resemble that of a bottle by a threefold operation: by blowing into the tube with greater force, *swinging* it backwards and forwards in the manner of a pendulum, and by a simultaneous constant rotary motion of the pipe round its axis. The globular form which the glass tends to assume under the influence of blowing, is converted into a long, thin egg-shape, *c*, by the swinging motion, and so much the more

Fig. 148.

as the lower temperature at the extremity is less favorable to the formation of a globe, than to the lengthening of the neck. The rotation round the axis of the pipe is an essential part of every operation in glass-blowing. The glowing mass of glass creates a powerful current of air in an upward direction, and the lower portion becomes cooled in consequence much more than the upper. This naturally creates an inequality in the resistance offered to the blowing, and the upper portion would be more expanded than the lower, if the cooling influence were not allowed to act upon all parts of the surface alike, by the revolving motion of the pipe, and this is particularly the case when the latter has to be held in a horizontal position. The mould, *d*, which is a simple cylindrical hollow block of wood or iron, is placed at the side of the workman who is blowing the pear-shaped vessel; into this he inserts the vessel as soon as it has acquired the proper thickness, in the manner represented in the figure, and by blowing forcibly into the tube, he presses the glass firmly against the sides of the mould, whilst, by a kind of jerking motion, the neck is drawn out to the proper length. The unfinished bottle, which as yet has no bottom or mouth, is again warmed in the working hole in such a manner, that the lower part only is heated, whilst the other part remains comparatively cool. In the meantime, another workman or a boy has attached a small quantity of glass to the ponty or pontil, which is also kept hot in the working hole. Both workmen now stand opposite to each other; and whilst the pipe and ponty are kept constantly turning, the latter is forcibly pressed against the middle of the lower part of the bottle, which is thus forced inwards, and an even edge is produced, upon which the bottle may stand steadily. The bottle remains for some moments between the two instruments, as shown at *f*, until, by the application of cold iron or a drop of water,

the neck can be separated from the pipe. This is an operation of constant recurrence in the glass-house, and is effected by a sudden change of temperature produced at the point of separation in the hardened glass, either by the cold application of a drop of water, or by the powerful heat of a red-hot iron, or thread of liquid glass from the pot. The point of separation must often be re-heated, to cause it to fly on the application of cold water. The bottle is now supported by the ponty, as shown at *e*, so that the neck can be warmed, and the sharp edges melted round without softening the other parts. A rotating motion is then given to the red-hot neck, the pipe being rolled backwards and forwards upon the knees of the workman. The bottle then revolves upon its axis, as if it were placed in a lathe, and it is only necessary to press the pucellas, *b*—Fig. 146—or an iron instrument like a turning chisel, against the mouth, to widen or reduce it to any required dimensions; the rim for strengthening the neck is formed from a drop of glass taken from the pot by the edge of the flask, and wrapped round the mouth in the form of a thick thread. The bottle, which is now finished, as shown in the last cut, is immediately carried on the ponty-rod to the annealing-oven by a boy, pushed into its proper place, and the ponty-rod is finally detached from the bottom of the bottle by a sudden sharp jerk. The place where the ponty was attached is perceptible in every bottle blown in this manner, by the sharp edges where the fracture occurred.

Large round bottles are blown without the use of a mould, and when of a very great size, like the carboys for sulphuric acid, the aid of steam is called in, by spirting about an ounce of water into the interior, and holding the mouth of the pipe with the thumb. Bottles in the shape of a flattened globe, are also made without any mould by simple blowing. The preparation of the mass of glass, the formation of the concave bottom and of the neck, is in this case effected in precisely the same manner as above; the swinging motion, however, must not be continued for such a length of time, as the bottles required are shorter. In blowing the belly of the bottle, the workman stands in front of a slanting board and presses the globe, as it is gradually formed by slow blowing, against the board at every half revolution of the pipe; the flat surfaces on opposite sides are thus produced.

As the greater number of bottles are necessarily sold with a legal stamp upon them, and as their capacity must be suited to the standard measures of the country, the fulfilment of these conditions presupposes an extraordinary degree of dexterity and correctness of eye in the blower. Attempts have consequently been made by many inventors to furnish the bottle-maker with a mould of such construction as would enable him to secure the formation of a bottle, perfect, both as regards form and capacity, at one single operation, without reliance upon his own correctness of sight. The use of moulds of this description, like that of RICKETS, which is easily managed, affords a great saving of time, and the repeated heating of the bottles is unnecessary. The mould consists of a body, which forms the belly of the bottle, and of four other parts, a fixed bottom-

piece with a movable piston for forming the concavity, and two movable pieces for the neck. Two treadles set these different parts in motion. As soon as the workman has introduced the hollow lengthened globe into the belly of the mould, by pressing with his foot upon the first treadle, he brings up the neck piece, then forces the glass into contact with all parts of the mould by a powerful blast, and finishes the bottle by working the second treadle, which forces the pestle against the bottom. On the removal of the pipe, the rim is all that remains to be perfected.—*Knapp*.

The circle of operations above described is continued with much quickness, four or five men being able to make a hundred wine bottles in an hour; and, with a few modifications, according to the size, shape, and purpose of the bottles, may be taken as a general exemplification of the mode of proceeding. The vicinity of the Tyne on the Wear is abundantly supplied with many of the requisites for bottle-making, and hence the manufacture is there largely carried on.

Champagne and Aerated Water Bottles.—The uses of bottle-glass do not require to be explained in detail, but it is necessary to say a few words with reference to bottles intended to resist a high pressure, such as those for holding champagne, and still more in this country for holding aerated waters, which are now manufactured in immense quantities. Bottles employed for such purposes undergo an internal pressure, which readily produces the fracture of weak vessels, and this occasions a loss which is always considerable, and often disastrous. It is evident that this might be diminished by testing all the bottles under a pressure the double of that to which they are intended to be subjected, and accordingly different machines have been invented for this purpose, by means of which water is forcibly pumped into the bottles, until the indication of the manometer shows them to have withstood a sufficient degree of force. DUMAS states that, from the experiments made by the *Société d'Encouragement*, champagne bottles were found to stand only when they were capable of supporting a pressure of twelve atmospheres. He adds that the mode of filling and annealing, as well as the form of the bottles, must exercise a great influence, which it would be necessary to find the means of estimating; also, that perhaps it would be desirable to leave a larger unfilled space in the bottles, and to use them only after a careful annealing in boiling water. KNAPP remarks, that although every bottle, when quite filled with water and containing no air, will burst in the belly from a slight blow on the cork, in consequence of the sudden force being communicated from the liquid to the sides, yet champagne bottles will often withstand a pressure of forty atmospheres and upwards, equal to six hundred pounds on the square inch.

II. WHITE BOTTLE OR CHEMICAL GLASS.—Under this head may be included white glass for medicinal bottles and chemical purposes, refractory Bohemian glass for tubing, *et cetera*, and foreign crown. The most beautiful material for bottles is furnished by flint-glass or crystal, but these are only intended for ornamental articles or vessels for the table, and will be alluded to under Flint-glass.

The general character of white bottle-glass consists

in this, that it is composed of purer materials than the green; decoloring matters are used, and the materials are selected as free from iron and alumina as possible. Moreover, in this case the glass is subjected to a thorough fining process. The following are given by KNAPP as general standards of composition for different varieties of glass of this description:—

FOR APOTHECARIES' PHIALS.

100	pounds	white sand.
30-35	"	potassa—impure.
17	"	lime.
110-120	"	ashes.
25-5	"	binoxide of manganese—cullet.

BOHEMIAN CRYSTAL FOR GRINDING.

100	pounds	white sand.
0-60	"	purified potassa.
8	"	chalk.
40	"	broken glass.
75	"	manganese.

SEMI-WHITE.

100	pounds	sand.
100	"	crude soda, containing lime.
100	"	cullet.
5-1	"	manganese.

100	pounds	sand.
30	"	potassa.
18	"	lime.

decoloring matters.

CLEAR WHITE.

100	pounds	sand.
65	"	calcined potassa.
6	"	fallen lime.
100	"	white cullet.
5	"	manganese.

WHITE GLASS FOR CHEMICAL PURPOSES.

100	pounds	white sand,
41.4	"	potassa,
17.5	"	lime.

Bohemian Glass.—The coarser qualities of this kind of glass are analogous in composition to bottle-glass, and are distinguished by comparative freedom from color, great lightness, and their very refractory nature, which renders them capable of resisting not only high heats, but sudden changes of temperature. Hence the value of this glass for chemical purposes, such as tubing, retorts, *et cetera*. Its lightness, and the almost total absence of coloration—when it is made with pure materials—cause it to be highly valued on the Continent for tableware, where it is also employed to make costly windows for fine buildings and carriages, for covering engravings, and in general for all those uses which require the glass to have a considerable thickness without coloration. In common with crown-glass, it is also peculiarly fit for optical instruments, in which it is employed to achromatize the flint-glass. These remarks apply to the finer qualities, for which DUMAS gives the following choice of proportions:—

Quartz in powder, or fine silicious sand,				
washed with hydrochloric acid,....	100.	110.	120	100
Purified carbonate of potassa,.....	60.	64	66	75
Very pure carbonate of lime,.....	20	24	25	50

In a Bohemian glass of old manufacture, DUMAS found

Silica,.....	69.4	=	36	oxygen.
Alumina,.....	9.6	=	4.48	} 9.04 oxygen of the bases.
Lime,.....	9.2	=	2.57	
Potassa,.....	11.8	=	1.99	

which would give exactly the proportion of 1 : 4 between the oxygen of the bases and that of the acid. On the whole, Bohemian glass may be described as a silicate of potassa and lime, with a small proportion of alumina, magnesia, and other ingredients. This will be obvious from the following analysis of a glass, taken by M. PERDONNET from a manufactory at Neuvelt, and analysed by M. GROS in the laboratory of the School of Mines at Paris:—

Silica,.....	71.6	=	37.1	Oxygen.
Lime,.....	10.0	=	2.81	
Potassa,.....	11.0	=	1.86	
Alumina,.....	2.2	=	1.02	
Magnesia,.....	2.3	=	0.89	
Oxide of iron,.....	3.9	=	1.20	
Oxide of manganese,.....	0.2	=	0.05	
			7.83	
			101.2	

Here it will be noted, that the silica contains about five times the aggregate oxygen of the bases. It will be observed also, that in Bohemian glass potassa takes the place of soda.

Tube-drawing.—Though tubes may be formed of any kind of glass, yet, for chemical purposes, and more especially for resisting a high temperature, the Bohemian or German tubes are the best. This may, therefore, be a fitting place to introduce some account of the curious operation of *tube-drawing*, which depends on the singular fact, that when a hollow lump of glass, for instance a globe, is drawn out whilst hot, the cavity in the interior is always preserved, even when the glass is drawn out to the tenuity of the finest thread. The operation is described by KNAPP in the following terms:—

Whilst one man collects the necessary quantity of glass on his pipe, and blows this out to a very massive globe, preserving a uniform thickness of the sides as much as possible—Fig. 149—the other attaches a drop of glass to a ponty-rod, and warms it on the fire by the side of the globe. Both instruments are then removed from the fire at once, and the ponty-rod is pushed forcibly against the globe in such a manner as to form exactly a straight line with the pipe, as represented in Fig. 150,

where A is the pipe, and B the ponty. This being accomplished, one of the workmen retires backwards as quickly as possible, to the distance of fifty, sixty, or one hundred feet. In this operation the globe at first shrinks, as is represented at *a*, in Fig. 151, and forms the commencement of the tube, which soon cools, and does not diminish in thickness, whilst the mass of glass is spun out by the constant drawing

Fig. 151.

where A is the pipe, and B the ponty. This being accomplished, one of the workmen retires backwards as quickly as possible, to the distance of fifty, sixty, or one hundred feet. In this operation the globe at first shrinks, as is represented at *a*, in Fig. 151, and forms the commencement of the tube, which soon cools, and does not diminish in thickness, whilst the mass of glass is spun out by the constant drawing

from the warm end. Continual rotation of the pipe and ponty-rod is here as necessary as in all the other operations of glass-blowing, or the part of the tube nearest the ground would cool quickest, and the tube thus assume an irregular form. This, however, does not prevent the tube, in consequence of its great length, from sinking in the middle like a stretched rope, and it becomes, consequently, thicker at the two ends, as is represented in Fig. 152. The curve in the tube is, however, remedied by placing it on a ladder before it has become perfectly set; it then straightens, and is

Fig. 152.

cut into lengths of four or six feet each, by taking hold of it with a cold pair of tongs. Tubes cool very uniformly, in consequence of their small amount of metal, and they are, therefore, not placed in the annealing oven. Lastly, the bore of the tube is dependent upon the length to which a given mass of glass is stretched, or, the length being the same, upon the mass of glass; the stoutness of the tube is, however, determined by the thickness of the sides of the original globe, as the relation between the thickness of the sides and the bore is not altered by drawing. Wide, thin tubes—such as are used for spindles, *et cetera*—must therefore be drawn out of a large thin globe, and *vice versa*: it is necessary, however, whilst the tubes are drawing to blow into them, that the sides may not sink in. —Knapp.

Foreign Crown-Glass.—The name of crown-glass is limited in this country to that which is formed into circular tables by the process of blowing; but the crown-glass of the Bohemian glass-houses assumes the variety of forms which belong to articles of luxury and art, and is generally moulded into different shapes, with a view to grinding and polishing. Regarded in this light, the foreign crown, properly so called, is rather distinguished by its composition, than by the methods of manipulation adopted in its manufacture. Like the coarser Bohemian glass, it is a silicate of potassa and lime; whereas, in the English crown, soda is employed, either in the shape of sulphate or carbonate. DUMAS analysed a good crown-glass of German manufacture with the following result:—

	Centesimally.	Oxygen.
Silica,.....	62.8	= 32.6
Alumina, oxide of iron and of manganese, 2.6		= 1.2
Lime,.....	12.5	= 3.5
Potassa,.....	22.1	= 3.7
		38.4

So that in this case the silica contained about four times more oxygen than the bases, and the quantity of oxygen in the lime and potassa, the two principal bases, was nearly the same. As this glass is chiefly manufactured for the same uses as crystal, it is better prepared by means of suitable moulds than by simple

blowing, partly because the forms required are frequently so complex as scarcely to admit of their being made by hand, and partly because the various indentations and projections upon the surface can be roughly given by means of a mould, and time and trouble are thus saved in the subsequent laborious operations of grinding.

As the beauty and value of this glass depend upon its absolute limpidness, the most careful selection of materials, both for the mixture and the pots, and a protracted and assiduous process of fining are required. Speaking of foreign crown-glass, DUMAS remarks that it is not an easy matter to arrive at a certainty of success in its manufacture. It is evident, he adds, that to obtain it without color, one must use potassa, and not soda. Even if the soda yielded a colorless glass, it should still be put aside on account of the facility with which glass having a soda base devitrifies, which would render the thick masses that require a long cooling quite milky, and full of crystalline and opaque nodules. Crown-glass should therefore be formed with a potassa base, and without oxide of lead; but lime must also be added. By forming a glass with merely a potassa base, there would be no danger of devitrification; but the glass would be soluble in boiling water, and consequently hygrometrical. This would be a serious disadvantage; for spectacle-glasses or other lenses so formed would constantly tarnish by the deposit of a film of aqueous vapor, and in the space of a few years would altogether lose their polish. This inconvenience is avoided by adding to glass with a base of potassa a certain quantity of lime; but then arises a not less serious evil—a proneness to devitrification. Glass with a base of potassa and lime, submitted to the prolonged annealing which thick masses intended for large lenses require, is apt to assume the milky aspect which indicates a commencement of crystallization in the mass. Thus the manufacture of crown-glass, as well as that of flint-glass—the two glasses indispensable for the preparation of achromatic objectives—both present the most serious difficulties, although from very different causes.

III. WINDOW-GLASS.—The glass which has long been in common use for window-panes is that which is generally known as *English crown-glass*, in the manufacture of which a large globe is first blown at the end of the pipe, and this is converted by a rapid rotatory motion into a circular plate or disc thickened at the centre. Until a comparatively recent period this was the only method employed in the manufacture of window-glass in this country; but latterly the Continental method has been extensively introduced, which consists in forming the globe into a cylinder, and then, after cutting it up in a direction parallel to the axis, flattening it out into a broad sheet, from which it has received the designation of *British sheet-glass*. *Plate-glass*, or that which is cast into sheets by pouring the liquid metal on a flat surface, is now beginning to be much used for the same purpose, especially for the windows of shops and fine buildings; but as the chief demand for plate-glass is still for mirrors and other similar articles, this will be treated under a separate head, and in the meantime

the term window-glass will be considered as confined to *English crown* and *sheet-glass*, which are composed of precisely the same materials, and differ only in the mechanical operations by which they are brought into form. Chemically speaking, they are the same, except that the nature of the crown-glass manipulation requires a smaller quantity of lime. Plate-glass, on the other hand, is formed with a larger proportion of alkali.

Composition.—The materials employed for the manufacture of English crown and sheet-glass—in other words, of window-glass—are chiefly silica, soda, and lime. This glass differs, therefore, from the foreign crown and Bohemian glass in the circumstance, that soda, as the cheaper alkali, is generally substituted for potassa. Sometimes, however, though rarely, a mixture of the two is employed. Alumina, oxide of iron, and oxide of manganese are also found in window-glass, but only as accidental ingredients. It is true, indeed, that when iron is present, as is almost always the case, the binoxide of manganese is purposely introduced to neutralize its effects; and a little arsenic is generally added to promote the decomposition of the other ingredients.

Mr. HENRY CHANCE, one of the highest authorities on this subject, remarks, that to lay down any standard proportions for window-glass is almost impossible, as no two manufacturers use the same; and even in the same works the melting powers of the furnaces may so far differ as to render necessary, for the production of the same glass, variations in the proportions of its elements. RICHARDSON and RONALDS give the following as the mixtures used in some English manufactories:—

	Pounds.	Pounds.	Hundredweights.
Sand,.....	560	448	16
Chalk,.....	154	146	5
Carbonate of soda,..	119	168	5
Sulphate of soda,.....	63	17	1.25
Arsenic,.....	2	2	0
Cullet,.....	448	448	16

The introduction of carbonate of soda, prepared from salt, into the glass manufacture of England, dates from the year 1831. Previously to this, kelp was employed as the source of alkali. In the meantime, the French manufacturers—released, in 1825, through the exertions of M. CLEMENT DESORMES, from the absurd veto which the government had pronounced on the sale of sulphate of soda—were enabled to turn their attention to the employment of this salt instead of the carbonate. They proceeded with caution in the introduction of the new ingredient—first mixing a small quantity of sulphate with a large proportion of carbonate; then half of each; and, finally, excluding carbonate, they adopted the sole use of sulphate, to the injury, doubtless, of the color of their glass, but gainers by the employment of a cheaper and more manageable material. Where absence of color, however, is an object, as in the manufacture of plate-glass, the exclusive use of carbonate of soda is still retained.

Proceeding cautiously in the steps of their foreign brethren, says Mr. CHANCE, the English glass-makers, after they had established the use of carbonate, made trial of the effect of a small quantity of sulphate of soda in a large quantity of carbonate. The carbonate gradually decreased, until at length, in the preparation of

blown window-glass, sulphate generally stood alone. But here, as abroad, the manufacturers of plate-glass still adhere to the carbonate. The preceding table of three different proportions for crown-glass evidently refers to a period when the carbonate still preponderated in this manufacture also. As the use, whether of carbonate or sulphate of soda, involves their preparation from common salt and sulphuric acid, attempts have been made to accomplish the direct union of silica and salt in the manufacture of window-glass, but have hitherto failed of success. The black bottles of Newcastle are made from common rock salt and sand from the bed of the river, with the carbonate of lime of the soap-works, and the tank waste of the alkali-makers; but for all better kinds of glass the circuitous combination of silica and alkali is still found necessary.

The following is a French composition, which gives, according to DUMAS, a window-glass of fine quality:—

	Parts.
Sand,	100
Chalk,	35 to 40
Dry carbonate of soda,	28 to 35
Broken glass,	60 to 180
Binoxide of manganese,	0.25
Arsenic,	0.20

Sometimes in larger quantity.

The oxygen of the bases in this glass is generally to the oxygen of the acid as one to four.

M. BASTENAIRE gives the three following compositions, which DUMAS considers too rich in alkali, and too poor in lime:—

	Parts.
I.	
White sand,	100
Good potassa,	65
Lime slaked in the air,	6
Fragments of white glass,	50
Arsenious acid,	1
Oxide of manganese,	0.30

	Parts.
II.	
Very white sand,	100
Good soda,	90
Red oxide of lead or minium,	5
Broken white glass,	100
Carbonate of lime,	5
Oxide of manganese,	0.40

	Parts.
III.	
White sand,	100
Good soda,	80
Carbonate of lime,	8
Broken glass,	110
Oxide of manganese,	0.20
Oxide of cobalt,	0.10

In none of these French receipts is the sulphate introduced, and therefore they may be referred to a period anterior to 1825, when, as already remarked, the sulphate began to be generally adopted in the French glass-works. DUMAS remarks that the object to be kept in view in employing this salt, is to render its decomposition by the silica as quick and easy as possible; and he adds, that this is managed by adding to the mixture a suitable quantity of charcoal, to transform the sulphuric acid into carbonic and sulphurous acids. Thus—

For each equivalent of dry sulphate of soda there

is required, therefore, one equivalent of charcoal, or else about six of charcoal for seventy-two of sulphate of soda. But to avoid coloring the glass yellow, only five equivalents of charcoal are employed. Thus, to produce a beautiful window-glass, continues the same writer, the following proportions are taken:—

	Parts.	Parts.
Sand,	100	100
Dry sulphate of soda,	44	58 to 75
Charcoal in powder,	4	4.5 to 5.5
Slaked lime,	6	13 to 15
Broken glass,	from 20 to 100	25 to 100

Mechanical Operations.—It has been stated that the difference between English crown and cylinder or sheet glass, is almost entirely in the manipulation. The above materials and proportions apply to both, inasmuch as the two are the same window-glass in the pot. The specific description of these two varieties, if they may be so distinguished, involves, therefore, only a series of mechanical operations, which do not strictly belong to the special object of this work. Yet, as the present article would be incomplete without such details, the Editor will here introduce a short account of both processes, beginning with crown-glass as the oldest; and, in doing so, he begs to acknowledge his obligations to Mr. HENRY CHANCE, by whose kindness he is permitted to present the reader with the following animated account of the mechanical part of the manufacture, from a paper which was read by that gentleman before the Society of Arts, in January, 1856.

1. *English Crown-Glass.*—Assuming one or other of the mixtures or compositions above given to be melted in the crown-glass pot, represented in Fig. 141, Mr. CHANCE begins by observing, that upon the surface of the melted glass is a ring of fire-clay, which, when the materials were thrown in, lay at the bottom of the pot, and after the completion of the melting, found its way upwards. This ring is of great service, for, floating in the centre of the pot, it prevents the exterior surface of the metal, or melted glass, which becomes stiff and stringy during the long period of working, from mingling with the interior or hotter surface, which thus remains throughout of a suitable consistency. The labor, also, of the skimmer, whose duty it is to clear the surface of the metal from any scum or dirt that may collect upon it, is considerably diminished by the ring, which, limiting the space from which the glass is drawn, limits also the space which it is necessary to cleanse, and any bubbles or impurities in the glass have a tendency to attach themselves to the ring.

The metal, or melted glass, having been brought, by the gradual cooling of the furnace, from a state of complete fluidity to a consistence capable of being worked, the *gatherer* dips the end of his pipe, or hollow rod of iron, into the pot inside the ring, and twirling it round its axis, to equalise the thickness of the gathering, collects upon the end, or nose, as it is technically called, a pear-shaped lump of glass, similar to that represented at A, Fig. 153. Resting his pipe upon a stand or horse, he turns it gently round, and allows the surface of the lump to cool, to fit it for a second gathering. So much glass is collected in this way, in successive layers, as will form a disc or table of about nine pounds weight,

and an experienced workman seldom fails more than an ounce or two in the correct weight. The lump completed, the gatherer, having cooled his pipe under a

Fig. 153.

trough of water, that he may handle it at any point, proceeds to roll the glass upon the marver, or metallic bed, until it assumes a conical form, the apex of the cone forming what is termed the *bullion-point*. A boy now blows down the pipe while it is still being turned by the gatherer on the marver, and expands the glass into a small globe. Having been heated, it is blown again, and assumes the shape of a Florence flask, as shown at B, and the future rim of the developed plate or disc is prepared by rolling the *piece*, as the glass under operation is technically termed, near the pipe nose, upon the edge of a marver. Again heated, it is now expanded by the blower into a large globe. During this expansion, it is important to keep the *bullion-point* exactly in the position which it previously occupied, in a line with the axis of the pipe. To effect this, the blower rests his pipe upon an iron support, and while he blows down the pipe and turns it round at the same time, a boy holds against the *bullion-point* a piece of iron terminating in a small cup. This operation is represented in Fig. 154. Again presented to the fire, by the peculiar manipulation of the workman, and the peculiar direction of the flame upon it, the front of the globe is flattened, the possibility of the globe collapsing during this operation being prevented by its rapid revolution round its axis. The piece now resembles somewhat in shape an enormous decanter, with a very flat bottom and a very short neck, as at C, Fig. 153. The *bullion-point* is still to be seen in the centre of the flat bottom, and its use now

Fig. 154.

becomes manifest. The pipe is laid horizontally upon an iron rest, and a man approaches, having in his hand the large rod of iron called the *pontry*, tipped with a lump of molten glass. Pressing this lump upon an iron point, so as to give it the form of a little cup, he fits it, when thus shaped, on to the *bullion-point*, to which it soon becomes firmly attached. The lump thus formed is called the *bull's-eye*, or *bullion* of the

developed plate. The incision of a piece of cold iron in the glass round the nose of the pipe, and a smart blow, soon detaches the pipe, leaving a corresponding hole in the flattened sphere, at a point exactly opposite the attachment of the *pontry*, as shown at D in Fig. 153. The blowing pipe thus removed, and carrying with it a piece of glass, is allowed to lie idle a few minutes, till the glass adhering to it has cracked off; it is then warmed, and carried back to the pot to repeat its course in a similar operation.

The open projecting end of the piece, which was next the now detached pipe, is called the *nose*, and gives its name to the furnace or *nose-hole*, where this nose is, on account of its thickness, heated almost to melting, with a view to the next operation. It is now that the glass

Fig. 155.

undergoes its last and most dreadful torture in the hands of a man who, with a veil before his face, as shown in Fig. 155, stands in front of a huge circle of flame, termed the *flashing furnace*, into which he thrusts his piece, rapidly, meanwhile, revolving his *pontry*. The action of heat and centrifugal force combined is soon visible. The nose of the piece, or hole caused by the removal of the blowing pipe, enlarges, the parts around cannot resist the tendency, the opening grows larger and larger; for a moment is caught a glimpse of a circle with a double rim; the next moment, before the eyes of the astonished spectator, is whirling a thin transparent circular plate of glass, which, but a few minutes before, was lying in the glass-pot, an indistinguishable portion of the molten mass. The sound of the final opening of the piece has been compared to that produced by quickly expanding a wet umbrella. In this way a flat circular disc, nearly sixty inches in diameter, or sometimes more, is produced, of almost uniform thickness, except at the point of attachment to the *pontry*, where there is a swelling called, as already stated, the *bull's-eye*. The glass at the edge of the disc is also in some cases a little thickened. Still whirling, the *table*, as it is now called, is carried off, laid flat upon a support called a *whimsey*, detached by shears, or otherwise, from the *pontry*, lifted into the annealing kiln upon a fork, E—Fig. 146—and piled upon its edge against the preceding table. The weight of so many tables pressing one against another, would cause the hindmost to bend; but this is prevented by the intervention of iron frames, or dros-

sers, which divide the tables into sets, the first dresser leaning against the wall of the kiln, the second against the first, and so on; and thus rendering each set of tables independent of those behind it for support. As the bull's-eye, or centre lump, which the ponty has left behind it, keeps each table from close contact with its neighbors, the air passes freely between them, and the annealing is completed with tolerable rapidity, varying from twenty-four to forty-eight hours, according to the number of tables in the kiln. From the kiln the tables are conveyed to the warehouse, having passed, since their first exit from the pot, through the hands of ten distinct workmen.

Such, with a few slight additions and illustrations, is the description of this most interesting process given by Mr. HENRY CHANCE. He adds that the process may be regarded as twofold—first, the development of the lump into a sphere; and, secondly, the resolution of a sphere into a circular table. Constant rotation of the glass, while in a yielding state, is an essential element of this process; as, if allowed to remain motionless, its symmetry would be immediately destroyed.

A table of crown glass of to-day, would scarcely recognise as of kindred origin a table of the earlier part of the present century. The principle of the process in each case was the same; it is the improvement of minute details that produces so different a result. To Mr. HARTLEY and Mr. CHANCE, who, during the years 1832 to 1836, gave to the manufacture of this glass their constant attention, is owing, in a great measure, its present status.

When the tables of crown-glass are drawn from the kiln, they are covered with a whitish film or *hum*. The history of this hum, continues Mr. CHANCE, is curious. It arose, probably, in the first instance, from the deposition of sulphur from the fuel upon the surface of the glass. It thus became associated with the process of annealing, and buyers fancied that the more hum there was upon the glass, the better was the glass annealed. The manufacturers of crown-glass, ever ready to accommodate themselves to the fancies of their customers, have taken the trouble to produce an additional hum by the introduction of sulphur in the kiln. The members, however, of the Glass Jury of the Paris Exhibition, not being in the secret of this hum, stoutly maintained that glass thus clouded must be bad glass, and that the hum was owing to the exudation of the alkali.

In the warehouse, the tables are laid upon a *nest*, or cushion, and are divided by the diamond of the splitter into two unequal parts—the larger half containing the bull's-eye. The diameter of the table is measured on the nest, the usual size being now about fifty-four inches, and weighing thirteen pounds. Tables have been made as wide as seventy inches, but the difficulty of manipulation, and the uncertainty of the result, render such sizes too costly to be general.

The splitter carefully examines each table before splitting it, and turns it round till he has brought it into the position in which he may split it to the best advantage, announcing at the same time its quality. The first quality is called *best*—the next, seconds—then thirds—fourths—CC—CCC or Irish—and tables con-

taining any very glaring defects, come under the denomination of *coarse*.

These variations in quality depend on the presence or absence, number and extent, of those defects to which, even in the best regulated manufactories, glass is unavoidably liable. Perhaps the glass has been badly melted, and is seedy—that is, full of little vesicles, to which the rotary motion has given a circular shape. Or the gatherer may have enclosed air within his *metal*, and a gatherer's blister is the result; or a pipe blister, or pipe-scales, or dust from the pipe-nose, or dust from the marver, or dust from the bottoming-hole, or dust from the nose-hole, or dust from the flashing-furnace, or bad bullions, or scratches, or music lines, may disfigure the table, or the glass may be crizzled, or curved, or bent, or hard, or smoky, or small and light, defects to explain which would be a long and dreary task. No wonder that tables of the best quality are few and far between, in some manufactories a forlorn hope never to be realized.

The difficulty of obtaining glass free from defects will account for what may at first astonish—the fact that the value of a table of the highest quality is three times that of the lowest.

The defects enumerated, many as they are, are instantly detected, even through the obscuring hum, by the splitter, who not only can descry faults invisible to ordinary eyes, but can refer each fault to a particular stage of the process, and to a particular cause in that particular stage, and the faults are registered accordingly. The nomenclature of defects is much facilitated by the mapping out of the table into certain ideal divisions, derived from shapes assumed during various periods of the process. The centre lump is termed the bullion, round this lies the bottom; next the bulge; the shoulder; the top, and the rim, or the outermost edge of the circle.

Independently, however, of these defects, there are certain other disadvantages under which even a faultless table of crown-glass must unavoidably labor. The cutting of a circle into rectangular sheets, must necessarily be attended with waste, while the bull's-eye confines those sheets to comparatively small sizes. Uniformity of thickness, also, except by the most skilful manipulation, is difficult of attainment. Wavy lines, termed music lines, forming a series of concentric circles round the bull's-eye, and owing to the treatment of the glass upon the marver, were formerly a common defect; but improvements in the process have in a great measure removed them.

On the other hand, extreme brilliancy of surface is a distinguishing characteristic of this glass, ascribed by some to the influence of the marver, by others to the effect of the flashing-furnace.

It is this brilliancy of surface which has enabled crown-glass to maintain in England its position against that formidable rival which is now to be briefly described.

Cylinder, or Sheet-Glass.—The above method of making window-glass has long been abandoned on the Continent, where the glass is first formed into a sphe-roid, the ends of which are cut off, so as to form a cylinder open at both extremities; this is then cut

lengthwise with shears, or a straight line is traced with a drop of water in the direction of the length of the cylinder, and over the line so traced a red-hot iron is passed, which immediately produces a very uniform crack or fracture along the whole length. The cylinder, thus split up, is then taken to the furnace to be spread or flattened out into a sheet. The glass so manufactured, though formed of the same materials as crown-glass, is coarser in texture, more wavy and dull, but allows of larger sheets being formed, since crown-glass can only be cut up into comparatively small panes, in consequence of its circular form and the central bull's eye.

M. BONTEMPS remarks that there is no evidence by which to determine the relative antiquity of the crown and cylinder glass processes. There is reason to believe, however, that even in this country the latter was the more ancient, although at a comparatively early period it was abandoned in favor of the rotary method. The cylindrical process is the only one mentioned by THEOPHILUS in the thirteenth century; and this method was adopted by the Venetians, as the more uniform thickness which resulted from it insured, in their colored glasses, a greater uniformity of tint. But in France, England, and the North of Germany, the cylindrical process fell gradually into disuse, as the demand for colored glass diminished, and at length in these countries the rotary principle exclusively prevailed. Bohemia, however, still retained the cylindrical method, which she had learned from Venice, and this method was reintroduced into France by M. DROLENVAUX in 1730 with great success. Hence speedily resulted, not only in France, but also in Belgium and the North of Holland, where the style of building required panes of large size, the general abandonment of the rotary principle, and the adoption of the cylindrical, which continues, as already stated, to be practised universally on the Continent at the present day.

In England the manufacture of crown-glass maintained its position, notwithstanding its abandonment abroad, and attained to such superiority over the spread or broad glass manufactured on the German principle, that the former was used for all houses of the better class, while the latter was confined to poorer dwellings. The inferiority of this spread glass, manufactured indeed on the German principle, but by no means so good as the German glass, tended to prejudice the public against all glass made by the cylindrical method. This prejudice was, however, gradually overcome, by the establishment in England of the manufacture of cylindrical glass, according to a process introduced from France, and from which resulted a glass that has entirely displaced the manufacture of spread glass. The latter was so called from the circumstance that the cylinder, unskilfully blown, and then cut open with shears, as already stated, was spread out immediately upon a plate of iron covered with sand. Hence not only was the thickness of this glass very irregular, but its surface very coarse.

The introduction into this country of the manufacture of cylindrical glass by the French method, was due to the MESSRS. CHANCE of West Bromwich, near Birmingham, and Mr. HARTLEY, now of Sunderland, but then

in partnership with the Messrs. CHANCE, who, on visiting in 1830 the works of M. BONTEMPS, near Paris, were much struck with the advantages of the glass made on this principle, and having secured the co-operation of M. BONTEMPS, commenced the process at their own works in the autumn of 1832. So great, however, were the difficulties to be overcome, that it was not till 1838 that the fabrication of this glass was completely established. Since that time there has been great progress, and the sheet-glass now manufactured in this country, though inferior in color, is in other points generally superior to that of the foreign teachers. On this point Mr. BANNATYNE, in the new edition of the *Encyclopedia Britannica*, says:—The French, Belgians, and Germans, having pursued the cylindrical system for the last fifty years in making their window-glass, have much improved the old method of making it; and as the parties who are now manufacturing this article in England—namely, the Messrs. CHANCE and Mr. HARTLEY—are crown-glass makers, and have imported all the improvements adopted in the making of sheet-glass in France, Belgium, and Germany, and combined with these the improvements which their experience as crown-glass makers had taught them during the same period, they have surpassed the French, Belgians, and Germans in sheet-glass, and can now compete with them in all parts of the world.

After this testimony, the following account of the process for making British sheet-glass, as given by Mr. HENRY CHANCE, one of the partners of the eminent firm above-named, will be received by the reader as of very high authority:—

Imagine, as before, a lump of glass collected upon the end of the gatherer's pipe. For the metallic table or marver is now substituted a block of wood, so hollowed out as to allow the lump, when placed upon it, to be expanded by the blower to the diameter ultimately required. The block, during this operation, is sprinkled with water, to prevent the wood from being burnt, and from scratching the glass. In the meantime the lump is slightly distended by blowing, and, having received the shape represented in Fig. 156, it is carried from the block to the blowing furnace, which is accessible through a number of holes or openings, each hole being allotted to a single blower. In front of the furnace, corresponding to each opening, is a stage or frame of wood, erected over a large pit or well about ten feet deep—as represented in Fig. 157—and these parallel stages are sufficiently apart to enable each blower to swing his pipe to and fro in a vertical plane, that the glass may run freely out, as the phrase is, to the required length. When the glass has been sufficiently heated in the blowing furnace, it is brought out, and held over the head while blown, until it assumes by its own weight the flattened form represented in Fig. 158. It is then swung round in a vertical plane, as well as backwards and forwards, and the blower at the same time, by blowing down the pipe, constantly keeps the lengthening cylinder full of

Fig. 156.

Fig. 158.

air. The first form which the glass assumes in consequence of the swinging motion is represented in Fig. 159. If the man were to blow without swinging, a

Fig. 157.

globe or sphere would be formed, as indicated by the dotted line. Uniformity of substance and of diameter is chiefly secured by the skill of the workman, who, when he finds the metal running out too freely, repeats the operation of holding the cylinder vertically above

Fig. 162.

Fig. 161.

Fig. 160.

Fig. 159.

Fig. 164.

Fig. 163.

his head, still keeping it well filled with air. These operations are continued until the cylinder has reached the length required, as in Fig. 160.

The next stage of the process is opening the end of the cylinder. The thinner kinds of glass are all opened by submitting this part to the fire, and at the same time forcing in air through the pipe, and stopping up its aperture with the thumb. The air is expanded by the heat of the fire, and bursts open the cylinder at the end, this being the hottest and most yielding part. The thick and uneven margin of the aperture thus formed is trimmed with scissors, and

the cylinder now appears as in Fig. 161. The aperture is then widened out to the full diameter of the cylinder with the pucellas, and by turning the cylinder to and fro with the opening downwards, until by the centrifugal force, and its own gravity, the yielding glass assumes a uniform diameter with parallel sides, as shown in Fig. 162.

The ends of the thicker cylinders, if these were opened in the furnace in the manner above described, would be so thinned out that a considerable portion would be wasted. An extra mass of hot glass is therefore incorporated with such cylinders at the end, which thus becomes the hottest and weakest part, without applying them to the furnace, and the air forced in as before bursts them open. The opening is then enlarged by cutting round it with scissors.

The neck or cap is now removed by supporting the cylinder on a chevalet or wooden rest, and turning the upper part two or three times in the curve of a bent iron heated to redness, as shown in Fig. 163; a drop of water allowed to fall on the heated line produces fracture and separation of the cap. Or, the same may be done by wrapping round the end of the cylinder a thread of hot glass, removing the thread, and applying a piece of cold iron to any part which the thread covered.

The cylinder, as it now lies upon the chevalet, is little more in weight than two-thirds of the lump of glass which the gatherer collected on his pipe. The quantity left upon the pipe-nose, with that which formed the cap of the cylinder, are nearly equivalent in weight to one half the cylinder.

The next operation is to split it open along its length in the manner represented in Fig. 164. Till of late this was uniformly done by means of red-hot iron and water—a method which is still practised on the Continent; but in the English glass-works, it is now effected with greater certainty and regularity by a diamond, which, attached to a long handle, and guided by a wooden rule, is drawn along the inside length of the cylinder. In performing this operation, it is important to make the line pass through, or in the neighborhood of, some notable defect or group of defects, if such be present, for the line forms two edges of the future plate, and defects brought to the edges are of lessened injury to its value. An object to be avoided is the black mark which the cylinder sometimes receives from the charring of the wooden chevalet, on which, while hot, it rested in the glass-house. If the diamond passes, inside the cylinder, over the space occupied by this mark on the outside, the cylinder will fly to pieces. The reason of this, says Mr. CHANCE, is not difficult to understand. The chevalet prevented, by its non-conducting tendency, that portion of the glass with which it was in contact, from cooling equally with the rest, and the particles at that point remained in a state of tension. A careful blower will never place any large defect in his cylinder in contact with the chevalet, being aware of the probable result.

The use of the diamond in dividing plain surfaces of glass, dates from the sixteenth century; but its application to the splitting of cylinders which had not undergone the process of annealing, was introduced only about twenty years ago by M. CLAUDET, the distin-

guished photographer, then a glass manufacturer. Previously, all such cylinders were split by a red-hot iron, and, even now, all cylinders of flashed glass, that is, of ordinary sheet-glass covered inside with a skin of colored, are still split in the same fashion. On the Continent the diamond is gradually replacing the use of red-hot iron, though the latter is still the method more generally practised.

Having been split along its length, the cylinder is now ready for the flattener, who, having prepared it by a preliminary warming in the flue by which it is introduced into the *flattening-furnace*, passes it, by means of a croppie, or iron instrument bent at right angles, on to the *flattening-stone* or *spreading-plate*, which ought, of course, to be perfectly even and smooth, as the soft glass moulds itself to the surface upon which

it is flattened by heat. The sandstone of Godstone, in Surrey, has been found to answer well for this plate, which, however, is usually covered with a *lagre* or sheet of glass. Upon this lagre, *BB*—Fig. 165—the cylinder, lying with the split uppermost, is soon opened by the flame passing over it, and falls back into a wavy sheet.

The effect of the heat is assisted by spreading out the softened sheet, *A*, with an iron ruler, *c*, introduced through an aperture in the furnace. The flattener now applies another instrument, a *polissoir*, or rod of iron,

c, Fig. 166, furnished at the end with a block of wood, *D*, and rubs down the waviness into a flat surface, often, upon a refractory piece, using considerable force.

Some cylinders are so distorted in the blowing that no rubbing can flatten them; but all, good, bad, and indifferent, pass through the same treatment. The flattening stone is now moved on wheels to a cooler portion of the furnace, and by the aid of the flattening fork, delivers its sheet to another stone, called the cooling stone. From this, when sufficiently stiff, it is again lifted, and then piled generally on its edge, in order to be annealed.

In 1842 the Messrs. CHANCE patented certain improvements, whereby, instead of at once removing the glass from the flattening to the annealing furnace, and lifting it to the cooling-bed while soft and liable to distortion, they flat and cool it by passing it through a succession of decreasing temperatures, so that it is not lifted until it becomes quite stiff and rigid. By this arrangement the workman can flatten the glass while the annealing is in progress, which could not be effected by the old method, because the temperature of the flattening kiln must be reduced with that of the annealing kiln, to which it is contiguous, thus leading to the successive heating and cooling of the kiln, and waste both of time and fuel. At Messrs. CHANCE'S establishment the flattening and annealing kilns are two circular buildings communicating with each other, and shown in

Fig. 165.

Fig. 166.

Fig. 167.

plan and elevation in Figs. 167 and 168. Each of the buildings consists of exterior and interior walls, *s*, the intervening space being a circular arched vault. In each vault is a cast-iron frame, moving on casters, and capable of being turned round by a winch on the outside, communicating with the shaft and bevil

wheels, *RR*—Fig. 168. The frame, *BB*, in the flattening kiln carries the flattening stones, *a*, and lagres, *A*, eight in number, and that in the annealing kiln a number of metallic wires, *G*, radiating towards the centre of the building, for supporting the sheets of glass. The flattening kiln is heated by the grate, *M*, and in order that the stones and

lagres, which will have cooled during the rotation, may be re-heated and arrive at the position, *R*, at a proper temperature, a second smaller grate is placed at *b*. If coke be used, a chimney at *T* will be required, but with

wood fuel it will not be needed. Partitions, *H*, are placed at certain intervals, to prevent the too rapid dissipation of the heat from those parts where it is most required, and to retard the entrance of cold air through

Fig 168.

the openings in the external wall. At the bottom of the partitions are spaces to allow the frame, with the stones and glass or the wires and glass to pass below. The space, *J*, on which the glass is shifted from the lagres to the wires, is lighted by gas. The kiln is worked in the following manner:—The cylinder of glass is first placed in the position, *N*; then in that of *L*; thirdly, it is introduced through the external wall, *d*, and placed on a stone, *E*, suspended over the lagres; it is lastly placed in the position *R*, on the lagre beneath. To prevent the cylinder rolling off, the stones are provided with a

Fig. 169.

ledge. This part of the kiln is shown separately in Fig. 169. The frame *B* is then turned round till the cylinder of glass occupies the position *C*, opposite the working hole, *D*, through which it is then flattened in the ordinary way. From *C* the glass passes round in the direction shown by the arrow, till it arrives opposite *J*, when it is shifted to the position *A'* on the wires, by the flattener using his instrument through the opening, *Q*; and after passing through the successive positions, arrives finally opposite *D'*, where it is drawn out fully annealed. Thus each sheet of glass, after having been flattened, remains on the stone during the time that other cylinders are being flattened, and before the sheet is lifted off the stone, it has passed through a gradually decreasing temperature, and has become rigid. The annealing is also carried on without lowering the temperature of the kilns by the movement of the frame, and the sheets, being isolated by the wires, become more quickly annealed.

Mr. HARTLEY, of Sunderland, introduced two improvements in this operation. One consists in making part of the floor of the flattening kiln to consist of a movable stone, about ten inches in diameter, on which the cylinder is placed, and by causing the stone to revolve on its axis, the cylinder is gradually exposed on all sides to the action of the fire, thereby avoiding the objection to the previous plan, where one side of each cylinder became so much hotter than the other. His other improvement consists in making holes, about the eighth of an inch in diameter, all over the flattening-stone. When the sheets of glass are to be polished, the absolute smoothness of the original surface is not

so much an object as to have them perfectly flat, and the air which lies between the common flattening-stone and the cylinder or spread sheet renders this difficult to accomplish; but by Mr. HARTLEY'S process the difficulty is overcome.

One of the most recent improvements is that of Mr. FARTHING, in which the kiln is heated by means of flues arranged under the floor, around the walls, and over the arch. By this means all deposit of dust or hard particles from the fuel on the surface of the glass is avoided, and any cheap kind of fuel may be employed.

To return to the flattened sheets: When annealed, they are drawn from the kiln, and carried to the warehouse, where they undergo examination. Being blown by a less complex process than crown, sheet-glass is liable, in the glass-house, to a less number of defects, but the subsequent process of flattening, notwithstanding the improvements above mentioned, often makes up the deficiency; and the manner in which a sheet, spared by one process, is disfigured by another, is described by Mr. CHANCE as sometimes curiously provoking. Standing upon the table of the *assorter*, he remarks, your eye lights upon a piece which, blown under an evil star, has imbibed in the glass-house every possible defect. The founder, skimmer, gatherer, and blower have all stamped their brand upon it. It is seedy—the vesicles, which were in the crown tables rounded by the rotary motion of the piece, are here elongated by the extension of the cylinder; it is stony, disfigured with stony droppings from the furnace; stringy, thin threads of glass meandering over its surface; *ambitty*, covered with stony speckles, symptoms of incipient devitrification; conspicuous with gatherers' blisters and blisters from the pipe—badly gathered; badly blown—thin here, thick there, and grooved with a row of scratches; and on this abortion the flattener chances to have exerted his most exquisite skill; it has passed through his hands unscathed, flat as a polished mirror, yet, from its previous defects, is entirely worthless. Next comes before you a piece whose beginning was miraculous—no seed, no blisters; it prospered under the hands of the gatherer and blower, and left the glass-house a perfect cylinder. But the croppie of the flattener marked it; the fire scalded it; dust fell upon the lagre and dirtied it; scraps from the edges of the preceding cylinder stayed upon the lagre, and stuck to it; the stone scratched it; and the heat of the annealing chamber

bent it. Such are the difficulties to which every cylinder is subject—those of the glass-house, and those of the flattening kiln. Not all, however, are such as these; there are good as well as bad, but the good are generally in the minority.

The qualities range thus—best, seconds, thirds, fourths, and H, the latter standing for horticultural, and including all coarse glass, such as may be applied to horticultural purposes. The difficulty of escape from defects renders the best quality, as in crown-glass, three times as costly as the common. The expense of production to the manufacturer is in each case the same; the materials, the labor, the fuel, the same for each. Success, therefore, clearly hinges on the proportion of good glass which a manufacturer can obtain. The six qualities of sheet-glass may each consist of six different thicknesses, forming thus, in all, thirty-six varieties.

When this manufacture was new in England, the size usually blown was thirty-six inches long, and twenty wide. The usual size now is forty-seven inches long by thirty-two wide, and cylinders are occasionally blown seventy-seven inches long; but large sizes and heavy weights are accomplished only by workmen of the first class. A sheet of this latter size, containing twenty-one ounces to the foot, would require for its formation a lump of glass upon the gatherer's pipe, of no less than thirty-eight pounds weight.

The size which sheet-glass can thus reach is obviously a great advantage, and adapts it to many purposes from which the limited dimensions of crown are excluded. It was this glass that covered the Great Exhibition in 1851. A cylinder was blown to cut, as the phrase is, forty-nine inches by thirty; this was subdivided into three panes of forty-nine inches by ten. About three hundred thousand of these, extending over a million square feet, and weighing upwards of four hundred tons, were the work of a few weeks, and this without absorbing or interrupting the ordinary produce of the manufacturer. The energy of the glaziers was equal to their task; eighteen thousand three hundred and ninety-two panes were fixed in the roof in one week by eighty men, one hundred and eight panes being accomplished by one man in a single day. It was the house of CHANCE and Company which executed the large order for the Exhibition, without materially affecting their power of executing their general orders, a feat almost unparalleled in the history of the manufactures of this country.

But sheet-glass has its faults as well as its virtues; it is devoid of that brilliancy of surface for which crown is so remarkable. It is subject, also, to undulations on the surface, the precise origin of which it is difficult to explain. Mr. SHAW, in his admirable lecture on the glass manufacture, as illustrated by the Great Exhibition, speaking of this defect, says—When the divided cylinder is softened by heat, and either allowed to flatten by its own weight, or flattened by the workman, the concave interior of the cylinder has to expand, and the convex exterior to contract, as the curved surface becomes plane. He adds, were this contraction and expansion to take place uniformly throughout the glass, the undulation in question would not occur, but since

one part invariably yields somewhat more readily than another, perfect flatness cannot be attained.

It is, however, more probable, in Mr. H. CHANCE's opinion, that this undulation is produced in the operation of blowing, and is due to the double movement of the particles of glass which accompanies the formation of every cylinder, the one movement being parallel to the axis of the cylinder, and the other in planes at right angles to that axis.

Grinding and Polishing Sheet-Glass.—A further development of the sheet-glass manufacture in England is the process of polishing and grinding this glass by machinery, whereby a new branch of manufacture has been established, which has furnished glass peculiarly applicable for purposes for which none previously existed. This improvement, which is the work of Mr. JAMES CHANCE, is characterized by M. CLAUDET as one of the greatest improvements which has ever been introduced in the manufacture of window-glass, as it has produced, at a cheap price, an article equal in effect to plate-glass, and by which houses can now be glazed with a glass that does not distort external objects, while, at the same time, when viewed from the outside, it has all the polish and fine appearance of plate-glass. To explain the merits of this invention, it must be recollected that the sheet-glass has the polish of its surface much injured by the mode of its production, and that a still greater defect arises from the inside and outside of the cylinder not being of the same length, so that when developed by the flattening operation either the one surface must contract or the other expand; and the result is a kind of undulating or wavy appearance called *cockles*. These cockles reflect and refract light in various directions, and the objects seen through the glass are necessarily distorted.

Several attempts, continues M. CLAUDET, were made in France and Germany to grind and polish this glass, in order to destroy these inequalities and imperfections. For this purpose sheet-glass had to be made considerably thicker, owing to its never being perfectly flat throughout its length and width, so that one corner or another, and even several points on the surface, were liable to be completely worn out before the end of the operation.

Mr. JAMES CHANCE conceived the ingenious idea of laying every sheet of glass intended to be ground and polished, upon a flat surface covered with a damp piece of soft leather. The sheet adhering completely to the leather after having been pressed against, produces, in fact, a vacuum, so that by the pressure of the atmosphere the whole sheet is maintained in a flat position. Two sheets having been placed in this manner, each on the retaining or sucking surface, they are turned one against the other in a horizontal position, sand and water being constantly supplied between them; and by means of the most ingenious machinery, the two surfaces rapidly rub one against the other in all directions, and are ground at the same time by the sand. When the grinding has been performed on one surface, the sheets are turned to have the other surface ground in the same manner.

The sheet being ground while it is kept perfectly flat, it is not necessary to wear out more than a thin

layer of the whole surface. Of course, after the operation, the sheet of its own elasticity resumes its former shape more or less curved, but the whole surface of both sides has a polish as perfect as plate-glass, and this is the desired condition for glazing purposes. Although the glass could not make perfect mirrors of a large size, on account of the slight curve arising from the flattening operation, still it may be usefully employed for small looking-glasses. M. CLAUDET states that this glass has all the perfection and qualities required for taking pictures by the collodion process, and for framing all photographic and other pictures, for which last purpose it is even preferable to cast plate-glass on account of its lightness.

Mr. JAMES CHANCE's invention is, therefore, one of the most important improvements in the manufacture of window-glass during the present century; and to him is due the cheap but beautiful glass now so generally used in glazing ordinary dwelling-houses—an article quite equal in effect to the expensive plate-glass which was formerly seen only in the windows of palaces and aristocratic mansions.

IV. PLATE-GLASS.—DODD justly remarks that a better name than *plate-glass* would be *cast-glass*, since the former is vague in its acceptation, and might be applied to any kind of glass in sheets, whereas the latter expresses the mode of manufacture of this beautiful article, which is formed by being *cast* or *founded* upon a smooth table while in a liquid state, and is totally independent of the process of blowing. It is not generally known, however, that originally all plate-glass was made by blowing; and that in this country it was not till 1773 that the British Plate-Glass Company first began to make plate-glass by casting, although this process had been in use in France for nearly a century. The method of blowing plate-glass was very similar in principle to that of sheet-glass, differing only in some mechanical contrivances to assist the workmen in handling so much heavier a piece. The plates formed by this method, however, were much smaller than can be executed by the casting process, which sometimes exceed ten feet in length, and are about half an inch thick. Plates have been cast as much as fourteen feet long by eight or ten feet in width, and some of enormous dimensions were shown at the Great Exhibition.

The principal consumption of plate-glass is for mirrors, the manufacture of which dates from the earliest introduction of glass-works into Europe. Mirror-glasses were for many years the object of an important commerce to Venice, the only city which could produce them. The manufactory, which was situated on the island of Murano, produced, however, only sheets prepared by blowing, and this was the process imported into France in 1665, along with the art of covering plates of glass with tinfoil, which had long been exclusively possessed by the Venetians. The largest mirror-glasses which could be made in this manner were about three feet in the side, and they were liable to the air-bubbles, knots, and striæ so frequent in common window-glass. All these disadvantages disappeared with the invention of the casting process which is now in use. ABRAHAM THEVART devised this bold me-

thod, as DUMAS terms it, and put it in practice at Paris in 1685. It was the same artist who founded in 1691 the celebrated manufactory of Saint Gobain in Picardy, which remained so long without a rival, and where perhaps the best plate-glasses are still made, though two or three other manufactories have been established on a very large scale, which renders the mirror-glass manufacture a very important object for France. In this country, as in France, the business is confined to a very few large establishments.

Composition of Plate-Glass.—This beautiful variety of glass is similar in composition to crown and sheet glass, the only essential bases being lime and soda; but in plate-glass the soda is introduced in somewhat larger proportion. So far as regards the purity of the tint, it would be attended with advantage to substitute potassa for the soda; plate-glasses would thus be freed from the greenish or bluish shade which they sometimes present, and, in this case, one might increase the proportion of lime, which is kept comparatively low in plate-glass to avoid devitrification. But soda is preferred to potassa for this description of glass, because it imparts a higher degree of fluidity, and because the impurities which it contains are more readily dissipated by the heat; so that the use of soda, though objectionable as tending to color the glass, facilitates both the fining and casting—two most important advantages in the manufacture. Subjoined is the analysis of a plate-glass by DUMAS:—

	Centesimally.	Oxygen.	
Silica,	75.9	=	39.4
Alumina,	2.8	=	1.3
Lime,	3.8	=	1.0
Soda,	17.5	=	4.4
	100.0		6.7

From this analysis it appears that the quantity of oxygen of the silica is about six times that of the aggregate oxygen of the bases. It will be seen, also, that this glass differs considerably from window-glass in the proportions; in the latter, for each equivalent of soda, there is always at least half an equivalent of lime, whereas, in plate-glass, for one equivalent of soda, there is only one-fourth of an equivalent of lime. In window-glass, putting the alumina and lime together, the oxygen of these earthy bases always exceeds the oxygen of the soda; in plate-glass the oxygen of the lime and the alumina constitutes scarcely the half of that of the soda. All these circumstances have the effect of rendering the plate-glass more fusible, more readily altered, and less hard than window-glass; but it is also less brittle, and less liable to be devitrified.

The preceding analysis is elementary and theoretical; the subjoined practical recipes are given in KNAPP'S *Technology*:—

Composition used at St. Gobain.	Composition according to Bastenaire.
100 pounds pure sand from Senlis.	100 pounds white sand.
35 pounds pure salts of soda.	60 pounds salts of soda.
5 pounds lime, crumbled.	13 pounds carbonate of lime.
100 pounds broken glass.	100 pounds broken glass.
Decoloring matters,	1 pound peroxide manganese.
	0.5 pounds smalt.

The following proportions, which have been used in England, are said to produce a superior quality of plate-glass:—

	Parts.
Lynn sand, well washed and dried,.....	720
Alkaline salt, containing forty per cent. of soda,.....	450
Lime, slaked and sifted,.....	80
Nitre,.....	25
Broken plate-glass,.....	425

These quantities produce one pot of *metal*, which yields one thousand two hundred pounds of glass.

The object for which plate-glass is chiefly manufactured requires in the materials the highest degree of purification, and the utmost care in the fabrication. A good mirror should reflect an image in its true and natural shape, and no distortion must occur, which invariably happens if lumps or waves in the glass unequally refract the light or produce irregular reflection. Moreover, the light must pass through the thickness of the glass before it is reflected from the metallic surface at the back; and as the thickness of the plates must correspond with their lateral dimensions, which are often considerable, it is evident that transparency and absence of color are points of great importance. It is true that in the last century this was a disputed question. MONTANEY advanced that the black color was preferable to all others for mirrors, and his theory appeared so plausible as to require a formal refutation on the part of ALLUT. It is evident that, unless the light were assumed to be reflected at the first surface, this theory is quite untenable; and even assuming the reflection to take place at the first surface, it would be necessary to give the glass, not only a black color, but a complete opacity, similar to that of the metals themselves, of which mirrors were anciently made; but this absolute opacity, in the case of glass, would be very difficult, if not impossible, to attain.

In the present day the object aimed at, by universal agreement, is to give the most perfect transparency to mirrors, and to destroy the slightest traces of coloration. With this view, not only must the metal or melted glass be thoroughly fused, but the original materials must be selected with very great care. The sands which enter into the composition should be very white and fine. In default of suitable sand, soft sandstone, white and well pulverized, is used. Flint and quartz, calcined and reduced to powder, are excellent materials for the purpose. Particular care must be taken in the choice and treatment of the soda, to avoid, as far as possible, the green tint which is peculiar to glass formed with this alkali, and which the thickness of the plate-glass betrays. It might be possible to counteract this evil to a certain extent by a perfect fining or purification of the soda, and by replacing part of it with potassa, to the amount of about one-fifth. If plate-glass were formed with potassa alone, instead of soda, it is to be feared that a glass necessarily so rich in alkali, would be hygrometrical, and would partake too much of the nature of soluble glass. Even the small proportion of potassa which, in the shape of nitre, usually enters into the composition of French plate-glass is found to give it a dampness, so that when two of these are kept together for any length of time, they can scarcely be separated. Mr. VARLEY stated at a meeting of the Society of Arts, that he was once shown some very large glasses by a London manufacturer, which were beautifully clear, but appeared

to be covered with steam, and this, when wiped off, appeared again. The manufacturer had applied to Professor FARADAY in hopes of learning how to cure this imperfection. On examining these glasses with a magnifier, the apparent steam was found to consist of very minute but long crystals, which shape indicated nitre, showing that so much potassa was used in the manufacture of the glass that it exuded. Now, repeated washings, which, with eight or ten feet glasses, is a serious labor, might much lessen the exudable matter; but the glass would thus become porous all over, and its power of transmitting or reflecting light would be diminished. What was still worse was, that such glass could never be wiped so as to remain clean, for the wiping filled up the pores with what should have been quite removed. This began again to exude in minute gummy dots, which continued to enlarge, and on again wiping, smeared the surface, rendering it difficult to clean. Soda is prone to dry and lose its water of crystallization; potassa, on the contrary, attracts moisture, and becomes liquid. Hence it would seem that soda must make the more durable glass, besides fulfilling the important conditions of rendering the vitreous composition more fusible and more easy to fine. The latter advantage arises from the fact, that the gall or sandiver of the soda-glass, consisting of sulphate of soda and chloride of sodium, is more volatile than potassa-gall, and is hence more readily got rid of from the open pots in which the glass is fused.

Melting and Fining.—Two sizes of pots are used in the manufacture of plate-glass—the larger for melting the vitreous mixture, and for keeping it long in a state of fusion—the smaller for receiving a portion of the glass to be fined and cast. The latter are termed cisterns, or in France *cuvettes*. The English pots and cisterns are of the same form as the pots used in the manufacture of crown-glass; and this is also the form of the French pot—Fig. 141; but in France the cistern or *cuvette* is formed square or rectangular—as shown in Fig. 170—and three pots contain the material for six small *cuvettes*, or for three large ones. These last are employed for mirrors of large dimensions—for example, of one hundred inches and upward. Lately, furnaces have been constructed for six pots and twelve *cuvettes*, eight small and four large ones. The small ones have the form of a perfect square, the large ones of an oblong rectangle. About the middle of the depth of the *cuvette*, A A, a groove or indentation, B, is formed, whereby the vessel is grasped with the tongs.

The ingredients for plate-glass were formerly fritted before melting; but this preliminary process is now dispensed with, the mixture being composed of such pure materials that it can be placed cold in the pot in three successive charges. The time necessary for the fusion and the fining is in France divided equally between the pots and the *cuvettes*. The material is left sixteen hours in each, and, at the end of these thirty-two hours, it is fit to be cast. During the melting of the mixture in the pots, the *cuvettes*

Fig. 170.

are placed empty in the furnace; but as soon as the whole charge is in a state of fusion, the cuvettes are removed by means of tongs, and cleansed from all impurity, and from the residual glass of the last operation by a scraper. They are then replaced in the furnace, and after a few moments' heating, the ladling or transferring operation commences. The surface of the metal in the pots is skimmed, and the liquid glass is transferred into the adjacent cuvette with a copper ladle, care being taken not to disturb any grains of sand or lumps that may have settled down at the bottom of the pot. Thus, as KNAPP remarks, at the very commencement a kind of double purification is effected—the infusible portion is left untouched, and the glass is well mixed by the agitation of ladling. This transferring process, which is termed in France *tréjetage*, requires two workmen, one after the other; each draws out the glass three times—whence the word *tréjeter*, to throw or cast thrice—and then plunges his ladle into cold water. The furnace is then shut, and the cuvettes are left to themselves, for the glass to fuse—that is to say, that the bubbles excited in the mass by the *tréjetage* may be disengaged, and the excess of soda be entirely volatilized. It has been stated that the melting is generally accomplished in sixteen hours; but the fining which succeeds the ladling process must be kept up quite as long, and extends indeed sometimes to twenty-four or even forty-eight hours before the bubbles are dispersed and no more alkali is volatilized, or until specimens of the glass exhibit in every respect a fit state for casting. This is not exactly a liquid state; but after the perfect melting has taken place, the glowing mass is allowed to lower its temperature a little, so as to acquire a slight degree of viscosity. With this view the fire is allowed to decline, and the glass acquires the proper consistency in three or four hours. To make sure of this, the end of a rod is dipped into the cuvette; the portion taken up is allowed to hang down, and by the form it assumes and other indications, the workman readily judges whether it has acquired the necessary consistence and is free from bubbles. This is termed *drawing the glass*.

Casting.—While the glass is acquiring the requisite consistence, attention must be given to heat the annealing furnaces, as well as the casting-slab or metal plate which is to receive the liquid glass. This table was formerly made of bronze; but the liability of this metal to crack induced the British Plate Company to try a plate of cast-iron, which was found to be quite successful, and even the large bronze slab at St. Gobain, which weighed fifty thousand pounds, and cost one hundred thousand francs, or £4000, has been discarded, and replaced by one of iron. The table, *TT*—Fig. 171—must be of longer dimensions than the largest plate; it varies from ten to twenty feet in length, with corresponding breadth, and is six to seven inches in thickness; it rests on a strong wooden frame or truck, *MM*, movable on casters, and sometimes running on a railway, along which it is wheeled from one annealing oven to another, since it is necessary that the table should be placed close to the oven or arch, *B*, into which the plate is to be removed for annealing after being cast.

With this view the height of the slab or table is made exactly on a level with the floor of the arch. Its upper surface is flat and polished, to mould the lower surface of the mirror; and, before the casting, it is heated by hot coals spread over it, and then wiped perfectly clean.

The annealing-ovens being heated to a brown-red, the casting-slab brought to a suitable temperature, and the metal or melted glass thickened to the requisite point for flowing readily and equably, the aperture into the cuvettes which are to be taken out is then opened; two workmen introduce tongs into the furnace, and grasp the cuvette by the groove shown in Fig. 170, while a third slides a large pincer under it. When this instrument is pushed well under the bottom of the cuvette, the workman draws it towards him, aided by the others with their tongs, which are supported on rollers. In this manner the cuvette is drawn to the mouth of the opening, where it is raised by a crane, placed upon a truck or low carriage, and removed to the casting-table. The melted glass being skimmed, the cuvette, *A*—Fig. 171—is then drawn up to a sufficient height

Fig. 171.

by the tackle, *DE*, and suspended above the upper end of the casting-table, where it is tilted over by means of the tongs, *CC*, and the metal is poured out on the table. The appearance presented by the molten sheet is now exceedingly splendid. The building being very dark within, the glowing liquid throws a strong light on the faces and persons of the workmen. In the meantime, the glass is prevented from running over the sides by ribs or rims of copper, *NN*, which are exactly equal in height to the intended thickness of the plate of glass; and when the cuvette has been emptied of its contents, a

massive hollow copper cylinder, *r*, three feet in diameter, and resting at each end on the side ribs, is set in motion. This cylinder, which weighs several hundred-weights, is moved by means of the handles which form a prolongation of the axis, and spreads the glass out into a sheet of uniform breadth and thickness. It would, however, overflow the sides, if this were not prevented by the workmen applying the iron pieces, *g g*, which form a dam at the sides, and precede the course of the rollers. Lastly, to prevent any impurity from contaminating the glass, a workman draws the washer, *h*, covered with cloth, immediately in front of the advancing sheet of fluid glass; the excess of glass pours over the front edge of the slab into a trough, *k*, filled with water, and finally the roller passes off and is received in the grooves, *l l*. A beautiful play of brilliant colors, comprising every imaginable tint, is exhibited by the glass immediately after the roller has passed over it; caused, probably, by a temporary oxidation of the surface.

Whilst the cuvette is carried back to the furnace to receive a fresh charge of glass, the two ribs are removed, and any blisters or seams or redundancy which may exist at the two sides of the plate are broken off; a thick flange of the still soft glass is then turned up at the end, *t t*, and a rake-shaped iron is applied to it, by means of which the plate is thrust forward into the annealing oven, *b*, where it rests upon sand. As the plate is not perfectly rigid when this is done, the force which must be exerted to push it over the floor of the kiln often produces considerable undulations on the upper surface, which subsequently disappear under the polishing.

While the introduction of the plate into the annealing arch is being proceeded with, other workmen are engaged in taking from the fining furnace another cuvette, which arrives at the casting-table at the moment when the preceding plate has just been introduced into the annealing oven. After filling the oven, all the openings are carefully stopped up with iron plates and clay mixed with sand. At the end of twenty hours, some of the pieces of iron are taken away; an hour or two afterwards more are removed; as the oven cools, more and more are taken away, and at last the whole of the clay and plates of iron which stopped the apertures are removed. When the hand can be placed on the glass plates without feeling much heat, they may be taken out of the oven. Such, at least, is DUMAS' account of the French method. But in this country the plates are allowed to remain in the oven, resting in a horizontal position, from five to ten days.

It has been stated that the temperature of the annealing kiln, when the plates are introduced, should be a dull red. If the kiln were too hot the plates would enter into a state of semi-fusion, and would get out of shape, or at least would adhere to the floor of the kiln, so that they could not be detached without breaking. On the other hand, if the kiln were too cold, the plates would be badly annealed, and might fly to pieces in the act of being taken out of the oven, or afterwards. The slightest change of temperature is sufficient to split into pieces plates which have been badly annealed. They break also when one proceeds to cut off the jagged

edge with a diamond. It almost always happens that, in plate-glasses badly annealed, the separation does not occur at the place where the incision has been made.

The annealing ovens, termed in France *carquaises*, are very large, and have several fire-places. The bed or floor is made of bricks, presenting in its whole extent a perfectly level surface. Sand must be sprinkled over the bed, that the plates may slide freely upon it, and encounter no impediment in shrinking or contracting.

Squaring, Grinding, and Polishing.—After being withdrawn from the annealing oven, the plates have to undergo the operations of squaring, grinding, and polishing. As taken from the oven, they are about half an inch thick, and present an irregular mottled appearance, roughened on the lower surface by the sand on which they have rested, and smoother, but not flat on the upper surface. The first process is that of squaring, or cutting them into their useful dimensions; for which purpose they are carefully examined, and the workmen endeavour, notwithstanding the imperfect transparency of the glass, to select those which appear to be free from defects, to be reserved for large plates, while such as show imperfections that cannot be removed by grinding, are picked out to be cut into smaller plates, transposing the faulty parts to the sides. The squaring is performed by passing a rough diamond along the surface of the glass, guided by a square rule; the diamond cuts to a certain depth into the substance, when, by gently striking the glass with a small hammer, underneath the part which is cut, the piece comes away; and the roughnesses of the edge then left are removed by pincers.

The plates having been squared, next undergo the processes of grinding and polishing. In these operations two plates are employed, one of larger dimensions, and one three or four times smaller, which are made to rub against each other. This was formerly done by hand, but is now almost entirely performed by machinery. The lower and larger plate is embedded in plaster of Paris, in a perfectly horizontal position, upon a table about two feet high, which is termed the *grinding bench*; the smaller plate is cemented upon the lower face of a swing table, made heavy by weights, and caused to traverse over the lower plate in such a way, that by a combination of a rotatory and oscillating motion, the relative position of the two plates is constantly changed. In adjusting the plates, a rough or rolled surface of the one is opposed to the comparatively smooth or casting-plate surface of the other, and the material employed to grind the surfaces is thrown upon the lower plate from time to time. River sand and water were formerly used for this purpose, but ground flint of different sizes is now substituted, as answering the purpose better. The machinery is set in motion by a steam-engine, and this process is continued until the ground plates exhibit a perfectly horizontal and even, though still unpolished surface. When one side of each plate has been sufficiently ground, it is loosened from the frame and turned over, so as to present the other surface to be ground in the same manner. Some degree of pressure is employed by loading the upper plate with weights, as the grinding of each side approaches to completion. The

process thus described used formerly to last three days, but the time is now much abridged. The greatest attention is required to complete the operation, with the surfaces perfectly level and parallel, for which end a rule and plumb-line are employed.

By means of this grinding, the plates are made level, but are still too rough to receive a polish. To fit them for this, they are now ground with emery powder of increasing degrees of fineness. When the plates become sufficiently smooth for this operation, there is a tendency to cohesion between the surfaces, which produces so much friction that when the work is done by machinery one surface will frequently tear the glass from the other. Hence hand labor has been generally employed in this part of the process. The lower plate is placed upon a stone bench covered with wet canvas, which holds it firmly in its place; the surface is sprinkled with emery and water, and a small plate, moved by the hand, is used as a runner or grinder. Women are generally employed in this operation, and are said to perform the work better than men, on account of their superior delicacy of touch, which enables them to use precisely the degree of force required, and readily to detect and remove gritty particles among the emery. Young girls are employed on small plates. About three sizes of emery are used, the different qualities being previously separated and assorted by suspension in water; and between every size the plates, canvas, bench, and hands are thoroughly washed. After the application of the last or finest emery, the plate has become quite smooth and partly polished. To dispense with the necessity of manual labor in this operation, Mr. BLAKE, of the Thames Plate-Glass Works, has recently introduced a machine which imitates the motions of the arms of the persons employed in smoothing, and works admirably.

The glass, although now perfectly even, appears opaque and deadened on the surface, and still requires the final polishing. To effect this, a piece of wood is covered with numerous folds of woollen cloth, having carded wool interposed between each two layers, so that the whole forms a tolerably hard but elastic cushion, which is fitted with a handle. The plate is embedded in plaster, as already described, and the cushion, being wetted, is covered with Venetian pink, which contains a small portion of oxide of iron, mixed with earthy matter, and is moved backwards and forwards on the surface of the plate, with considerable pressure. This rubbing is now generally performed by machinery, as hand-polishing is tedious, and is apt to produce a wavy appearance; hence machine-polished glass is to be preferred.

In 1856, a patent—communicated by ALBERT BROUGHTON, ALEXANDER LINDSAY, and JOHN RUTHVEN PLATT, all of New York—was taken by WILLIAM EDWARD NEWTON, of the Patent Office, Chancery Lane, London, for an improved method of polishing the surface of glass, stone, metal, or other materials capable of being polished by friction. The distinguishing principle of this method consists in grinding and polishing the flat surfaces by means of a rotating plane of glass, metal, stone, or other suitable material, the substances of which the surfaces are to be ground or polished being held in a frame in such a man-

ner, that the friction, exerted by the rotating plane upon the surfaces of the substances under operation, will cause them to rotate with a slower motion upon their own centres. The form adopted as most convenient for the grinding and polishing surface is circular; it therefore generally consists of the upper surface of a circular table or wheel, which may be of cast-iron, and is secured firmly at the upper end of a vertical shaft, which is supported in suitable bearings in a strong framing of timber or iron. The upper end of the shaft is not allowed to stand above the table, and therefore the article to be polished will be allowed to pass over its centre. Rotary motion is communicated to this circular table by means of suitable gearing. The apparatus for holding the plate of glass to be ground and polished consists of a plate or frame of metal or wood, having a rim all round the lower side, within which the glass is received in a bed of plaster of Paris. This plate or frame is connected with a perpendicular spindle which is capable of being moved nearer to or further from the centre of the rotating circular table. The grinding and polishing operation is effected with the aid of sand, or any common polishing material. To commence the operation, the plate of glass, having been secured in its bed or frame, is placed on the rotating circular table, and the holding plate or frame is connected with the long lever by means of its spindle. Rotary motion is now given to the circular table, and when the sand or grinding material is properly distributed, the friction produced on that part of the plate of glass which is at any time on that side of the spindle of the holding frame which is furthest from the centre of the table, being greater than that on the part which is at the same time on that side of the spindle nearest the centre of the table, causes the plate to rotate in the same direction as the latter. The sand or grinding material, when a fresh supply is applied, will always distribute itself evenly after a very few revolutions. The grinding may be regulated by a screw and nuts on the spindle of the holding frame, so as to produce a pressure on the plate, additional to what is produced by its own weight, and the weight of the plate or frame and other parts of the holding apparatus, or to take off some of that pressure. The patentee alleges that, by producing the rotary motion of the glass to be ground and polished, by means of the friction of the grinding or polishing surface, an evenness and smoothness and freedom from scratches are obtained, that cannot be produced when the rotary motion is positive, or produced by gearing, as in other polishing machines. The reasons assigned for this are as follow:—In the former case, the grinding or polishing surface and the surface to be ground or polished undergo an infinite transposition, while in the latter, they are frequently in precisely the same relative positions; again, when the motion is produced by friction, it is found to be steady and free from the tremor which is produced when an independent and positive motion is given.

The Editor is informed by Mr. FINCHAM, the active and intelligent manager of the British Plate-Glass Works, that the preceding process acts admirably, and is sure to supersede all those hitherto in vogue. It is daily working under Mr. FINCHAM's superintendence.

Mr. BESSEMER some years ago proposed a new method applicable to the whole process of casting, grinding, and polishing plate-glass. Dispensing with the use of cuvettes, he pours the melted glass directly from the pots between two rollers, placed at a certain distance apart, and kept cool by a current of water passing through them. This insures a uniform thickness in the glass. The furnace employed by Mr. BESSEMER is a reverberatory with a low arch, and the pot, which is of very large dimensions, is set upon a movable siege composed of masses of firestone firmly cemented together. The pot and siege run upon four wheels, by means of which they are readily moved out of the furnace, to empty the contents of the pot between the two *forming* rollers already alluded to, and, after passing between these, the glass is received between two *finishing* rollers placed closer together, and moving with accelerated speed, so that, on emerging from the latter, the glass appears smooth and flat, though wanting in polish. The plate now slides down a curved surface upon a flat table, and, when sufficiently cooled to become rigid, it is transferred to the annealing kiln, which is heated by a current of hot air obtained from a chamber situated between the furnace where the glass is melted and the chimney. A saving of fuel is thus effected, the heat is more easily regulated, and the articles to be annealed are not subject to injury from the dust and products of combustion of the fuel. The polishing, according to BESSEMER'S method, is performed by laying the plate of glass upon a slab of slate placed perfectly horizontal upon a bed of brick-work, and causing an endless belt of gutta percha, covered with felt and polishing material, to pass rapidly over the surface of the glass in contact therewith, and to traverse at the same time slowly across the plate by a lateral motion at right angles to the line in which the belt moves over its drums. The belt is of the same length as the sheet to be polished, and is pressed upon the entire surface of the glass by a number of small rollers. The continuous action of the strap in one direction renders it unnecessary to cement the glass to the table, which is effectually prevented from shifting its position by a raised rib or stop let into one end of the table.

By the grinding and polishing, the plates are reduced in thickness as much as one-third, and in some cases one-half. If any radical defects exist in the glass, these are only heightened by the polishing, and hence a second and more careful examination and selection of the plates is now made. In fact, in every stage of the manufacture, the experience of the workman is called for, to determine whether any and what imperfections appear, and how they are to be removed; and as, on the one hand, no manufactured article would betray the existence of defects more readily than a large sheet of plate-glass, so, on the other hand, the most sedulous attention is paid to the detection of such defects when they appear in the course of the manufacture. Those which are still found defective after the polishing, are cut up into smaller plates, and polished again, while the perfect ones, when destined for mirrors, are subjected to the final process now to be described.

Silvering of Mirrors.—This designation is a misnomer, there being no silver used in the common method of performing the operation; but a compound of tinfoil and mercury, or quicksilver, whence probably the mis-appellation. The operation is commenced by spreading a sheet of tinfoil, which must be of somewhat larger dimensions than the plate to be covered, upon a flat stone or slate slab, termed the *silvering table*, and brushing mercury over it. When the surface of the tinfoil is uniformly covered, more mercury is added till it covers the metallic sheet to the depth of one-sixth or one-fourth of an inch. A brilliant surface is then produced upon the fluid metal, by skimming aside the grey coating of oxide with a wooden rod. The plate of glass is now introduced by pushing it forward horizontally from one side of the table, with the longest edge foremost, and so that this edge always dips below the surface of the mercury. By this means dust and air are totally excluded; whereas, if the plate were let down perpendicularly upon the mercury, more or less of both would certainly be enclosed between the glass and the amalgam. On the contrary, by sliding it forward in the manner described under the surface of the mercury, the pure metal alone is brought into contact with the glass. To get rid of the excess of quicksilver, the plate or mirror is loaded with weights, and the table is inclined at an angle of ten or twelve degrees, when most of the uncombined mercury flows away. The last portions are removed by placing the plate in an upright position, and in the course of three or four weeks a dry permanent coating of tin amalgam is left on the glass.

A great disadvantage attending this operation is the serious detriment to the health of the workmen from the vapor of the mercury; another objection is the very considerable time required to complete the work; and, lastly, the process is subject to frequent failure from different causes: the plates often break under the pressure of the weights, and, when set on edge, drops of mercury sometimes trickle down, and carry the amalgam with them, producing curved streaks, technically termed *worms*, so that it becomes necessary to re-silver the whole mirror. The amalgam, also, is liable to spoil by crystallization, and is easily injured by carriage. A process proposed by DRAYTON, and tested by FARADAY and WARINGTON, is free from these defects. It consists in employing a *silvering fluid*, obtained by mixing ammonia with nitrate of silver, filtering the mixture, and adding to it an alcoholic solution of oil of cassia. The proportions are one ounce of nitrate of silver, three ounces of alcohol, of the strength of 87 per cent., and twenty to thirty drops of cassia. This fluid has the property of depositing *bright metallic silver* on the addition of what is termed the *reducing liquid*, consisting of a solution of one part oil of cloves in three parts alcohol. The term *silvering* is, therefore, strictly applicable to this process, which is performed by surrounding the plate of glass, after being perfectly cleaned, with a rim of putty, and pouring upon it a layer of silvering fluid to the depth of one or two lines. The oil of cloves solution is then added, and, more or less rapidly, in proportion to the quantity of this solution

employed, a film of brilliant metallic silver is deposited, and attaches itself firmly to the glass. The coating succeeds best when a very small portion of the reducing liquid is used, so as to cause the reduction to proceed slowly. To cause the precipitation of four and a half ounces of the solution of silver, from six to twelve drops of the reducing liquid are sufficient; and so thin is the film of metal thus deposited, that a square foot of it only weighs from twelve to eighteen grains. The principle of the process consists in deoxidizing the oxide of silver, by means of the volatile oil, which is effected without any evolution of gas, that might destroy the continuity of the metallic coating, while the nitric acid disengaged from the oxide of silver enters into combination with the ammonia.

Great as may appear the advantages of this process, it has not been applied extensively by the manufacturers of mirrors, partly on account of the difficulty of obtaining, by this means, a perfectly clear unspotted surface, and partly on account of the darker color of the silver coating, which gives a black effect to the mirror. This black appearance is probably due to the shade of the silver, although it has been also ascribed to the very perfection of the coating, and the precision with which it reflects the rays of light, whereas the ordinary coating of tin amalgam is crystalline, and reflects the light to the eye in almost any position.

The mixture now employed by Mr. DRAYTON is somewhat different from that above given, and consists of one part of ammonia, two parts nitrate of silver, three parts water, and three alcohol; this solution, being filtered, is mixed with one-fourth part of grape sugar dissolved in weak spirit. This method, or one very similar, is stated by PELOUZE and FREMY to be now successfully practised at Paris. The exact proportions given by them are as follow:—Six hundred grains of pure neutral nitrate of silver are dissolved in one thousand two hundred grains of water. To this solution are added:—First, seventy-five grains of a liquor prepared from twenty-five parts of distilled water, ten of sesquicarbonate of ammonia, and ten of ammonia, of specific gravity 0.980; second, thirty grains of ammonia, specific gravity 0.980; and, third, one thousand eight hundred grains of alcohol, specific gravity 0.850. The mixture is left at rest to become clear. The liquid is decanted or filtered, and a mixture of equal parts of alcohol—specific gravity 0.850—and of oil of cassia is added in the proportion of one part of this *essence of cassia* to fifteen parts of the argentiferous solution; the mixture is agitated and left to settle for several hours, after which it is filtered. Just before pouring it upon the glass to be silvered, it is mixed with one-seventy-eighth of its bulk of *essence of cloves*—composed of one part of oil of cloves, and three of alcohol, specific gravity 0.850. The glass having been thoroughly cleansed, is covered with the silvering liquid, and warmed to about 100°, at which temperature it is maintained for two or three hours; the liquid is then decanted, and may be employed for silvering other glasses. The deposit of silver upon the glass is washed, dried, and then varnished.

VOHL proposed to form the silver coating for the

interior of glass balls, *et cetera*, by dissolving gun-cotton in caustic potassa, with the aid of heat, adding to the brown solution a few drops of nitrate of silver, and the ammonia, until the precipitated oxide of silver is re-dissolved. This mixture is introduced into the glass ball, or other article to be loricated, and heated in a water-bath, when, after a certain time, the mixture becomes blackish-brown, froths up, and deposits all the silver upon the glass, forming a mirror which is said to reflect the light with surpassing brilliancy.

V. FLINT-GLASS.—This compound, which is commonly termed *crystal*, from its great resemblance to the natural production known as rock-crystal, is chiefly manufactured into articles of domestic use and ornament, such as tumblers, decanters, wine-glasses, vases, drops for chandeliers, *et cetera*. In consequence of its great transparency and high refractive power, it is also formed into lenses for optical instruments. On the Continent the term flint-glass is almost exclusively applied to glass which is expressly manufactured for the latter purpose, and *crystal* is employed as the more comprehensive designation for glass containing lead, of which flint or optical glass is regarded as a variety. In this country, flint-glass and crystal are used as synonymous terms, and that particular variety of this description of glass which is manufactured for optical purposes is termed *optical-glass*.

Flint-glass is so called from the circumstance that, formerly, flints calcined and ground were employed in the manufacture as the source of the silica; but for many years past, Isle of Wight, Lynn, or Reigate sands have been substituted. These sands are not only more free from iron, but less expensive in the preparation than flints, when washed and calcined. Not only in this respect is the name inapplicable. To convey a correct idea of its composition, it ought to be termed lead or metallic glass, as the presence of a new element, *lead*, is that which distinguishes flint-glass or crystal from the different varieties of glass already mentioned. It is also distinguished from English crown and plate-glass by the use of potassa, instead of soda, in the manufacture.

DUMAS remarks that, by all the old writers, colorless glass, whatever be its nature or composition, is designated indifferently under the name of *crystal*. Thus, under this common designation, were confounded glass with a simple base of potassa, glass with a base of potassa and lime, and lastly, glass with a base of potassa and lead. It is necessary to be aware of this confusion, if one wishes to read with profit the old works on glass-making. At the present day, the term crystal or flint-glass is reserved to denote the double silicate of potassa and lead employed for the purposes already mentioned.

This beautiful variety of glass is admitted on all hands to be of English origin. Its invention was a natural and almost necessary consequence of the use of coal in the English manufactories—a usage which goes back to a very remote epoch. To prepare white glass in an open pot, with coal as fuel, is a problem which admits of being solved at the present day, but which could not be so at an early period. To protect the glass from the contact of the smoke which blackened

it, it was necessary to convert the common pot into a retort with a short neck, which presented its mouth outside the furnace. But under this condition, the vitrification became too difficult for ordinary glasses; it would have been necessary to increase beyond measure the proportion of alkali. It was essential, therefore, to find the means of increasing the fusibility of the glass, without rendering it deliquescent; and this was accomplished by means of a suitable addition of protoxide of lead. The beauty of the product soon assigned it a high rank among the different varieties of glass, and the manufacture of it was not long in extending even into countries where coal is not used. But in these localities the manufacture could be conducted in common pots, taking care to manage the wood fire, so as to avoid all production of smoke, and modifying slightly the proportion of the substances employed.

Flint-glass, however, is not entirely a modern invention, or, at least, if it was necessary to re-invent it, it is certain that it was known at a very remote epoch. This is demonstrated by the analysis of the ancient glass known as *Virgil's mirror*, an operation performed in 1787 by M. FOUGEROUX DE BONDAROY. This mirror, weighing thirty pounds, polished on both faces, transparent, but colored a yellowish green, contained at least half its weight of oxide of lead, and exhibited, moreover, all the characters of crystal. It had been preserved in the treasury of Saint Denis in France from the time of its fabrication, which assigns to its manufacture an epoch long anterior to the discovery of modern crystal. It is evident, indeed, that the name applied to the mirror is not correct, and proves nothing—that it did not belong to VIRGIL, and that it could not claim an antiquity so remote. This article only proves that the method of making lead-glass had been long known, and that the processes of the manufacture must have been well understood, since at that time a mirror could be formed of a size which would be deemed remarkable even at this day, and that the secret had been lost during a long succession of years. It may be affirmed, indeed, that the *colorless* crystal or lead glass of the present day, or, in other words, a crystal possessing that quality which constitutes its chief beauty and value, is entirely of modern invention. It is very natural to suppose that the method of making a colored crystal like Virgil's mirror might be known to many mediæval chemists, without assuming that they equally knew how to prepare a pure and colorless crystal like that now manufactured under the name of flint-glass.

Composition and Properties of Flint-Glass.—Five elementary analyses of crystal or common flint-glass have been given at page 192. The table in the same page, in which flint-glass is associated with strass and enamel, refers to that variety of flint-glass known as optical glass. From the former analyses it will be seen, that the composition of common flint-glass, after deducting the extraneous constituents, may be expressed by the following formulæ:—

- I. $\text{K}_2\text{O}, 2 \text{SiO}_3 + 3 (\text{PbO}, 3 \text{SiO}_3).$
- II. $3 (\text{K}_2\text{O}, 3 \text{SiO}_3) + 4 (\text{PbO}, 3 \text{SiO}_3).$
- III. $2 (\text{K}_2\text{O}, 2 \text{SiO}_3) + 3 (\text{PbO}, 2 \text{SiO}_3).$
- IV. $3 (\text{K}_2\text{O}, 2 \text{SiO}_3) + 3 (\text{PbO}, 2 \text{SiO}_3).$
- V. $\text{K}_2\text{O}, 2 \text{SiO}_3 + \text{PbO}, 2 \text{SiO}_3.$

In one case, therefore, triple silicates are the proximate constituents of the glass; in the others, double silicates. In fact, the proportions of the three essential constituents, namely, silica, potassa, and oxide of lead, vary according as the melting furnace is heated with wood or coal. In the latter case, the proportion of oxide of lead is increased. The following analysis by DUMAS has been already given at page 192, but is here repeated, to show the proportion of oxygen in the bases, as compared with that of the silica or silicic acid.—

	Centesimally.	Oxygen.
Silica,	56	29
Limé,	2.6	0.72
Oxide of lead,	32.5	2.25
Potassa,	8.9	1.50
	100.0	

Here the oxygen of the bases is to that of the acid as 1 : 7. In the following analysis by M. BERTHIER, of a Vonêche crystal made with coal as fuel, the proportion is nearly 1 : 9 :—

	Centesimally.	Oxygen.
Silica,	61.0	31.7
Oxide of lead,	33.0	2.3
Potassa,	6.0	1.0

These two analyses show, beyond all doubt, that the law of saturation of crystal or lead-glass varies within wide limits.

Many metallic oxides are capable of combining with silicic acid, and thus furnishing silicates which readily mix with alkaline silicates; but almost all these are colored. Till lately, the protoxide of lead and the oxide of bismuth were regarded as the only oxides capable of yielding silicates with little color, and, consequently, colorless glasses, by their mixture with the silicate of potassa in a proper proportion; but a *glass of zinc*, which had a very pleasing and white appearance, and was specially suited to achromatic purposes, was the subject of a reward at the Great Exhibition of 1851. This glass had the remarkable property of being of greater specific gravity, and much more pure and pellucid than lead-glass. It is to be expected, therefore, that the former may come into general use. On the contrary, the oxide of bismuth is much dearer than that of lead, and hitherto the latter has been alone employed in the manufacture of common crystal.

Crystal or flint-glass well prepared is almost without color. It is more transparent, more brilliant, and heavier than plate or window-glass. It excels the fine Bohemian crown-glass in refractive power and easy fusibility, although the latter is harder and more completely colorless. Flint-glass, of not less than the usual density of 3.200, well polished by the lapidary, is considered the nearest approach to the diamond. It owes its brilliancy and high density to the silicate of lead; but as the latter is itself yellow, it communicates a yellowish tint to the crystal when it preponderates over the alkaline silicate beyond a certain limit. There is also another reason for avoiding to use too much of it. The silicate of lead is much softer than the alkaline silicates. In too large quantity, therefore, it renders the glass so easy to scratch by the slightest friction, that it could not be employed for most of the articles

of domestic use or luxury into which it is fashioned. Moreover, this addition rendering it both heavier and more costly in the manufacture, would be at least useless, even if it were not absolutely prejudicial, for the reasons already mentioned. It is a common mistake to suppose that great density or *weight* is an advantage in crystal for articles of common use. It is, on the contrary, as DUMAS justly remarks, a real inconvenience, and, in the most favorable view, can only be considered as a ready means of showing that the crystal or flint-glass contains enough of silicate of lead to impart to it all the other qualities which give it its peculiar value, and render it preferable to other glasses for certain purposes.

As lead affords the only metallic oxide which is usually employed in the manufacture of flint-glass, so potassa is the only alkali which can be successfully associated with that ingredient to yield a colorless crystal. The silicate of soda always communicates a blue or green tinge, which would become more perceptible and disagreeable in the thick articles usually manufactured of crystal. If this thickness were much reduced, the silicate of soda might, so far as color is concerned, be used in the manufacture; but as crystal vessels are generally intended to receive mouldings or cut ornaments, they do not admit of being made thin in the sides. The annealing, also, would become a difficult operation in vessels of considerable size without a proportionate thickness. Crystal is so fusible that it is not easy to prevent such articles from sinking in, or collapsing, during the annealing. This kind of glass is, therefore, almost exclusively confined to the manufacture of thick articles; and hence it is only the colorless silicates that can be used—that is to say, those of lead, or zinc, and potassa. It is stated, indeed, that M. BONTEMPS uses soda instead of potassa, or a mixture of the two, in his recipe for optical glass; but this is an exception to the general rule, and requires explanation. The following practical recipes are given by M. BASTENAIRE for a good common flint-glass, the one with coal, and the other with wood as fuel:—

	With coal as fuel.	With wood as fuel.
	Pounds.	Pounds.
Sand—washed and calcined, . . .	100	100
Minium,	70	45
Purified potassa,	30	35

In addition to these, cullet or broken glass is added at discretion, and saltpetre or arsenic is used as a decoloring material. It will be seen that, when coal is used, the sand, red lead, and potassa are nearly in the proportions of 3 : 2 : 1; but that, when the composition is fused in open pots, with wood fuel, the proportion of the red lead is much diminished. The following composition, in which the above-mentioned proportions of the principal ingredients are exactly adhered to, is given by Mr. APSLEY PELLAT, as yielding a highly pellucid and transparent flint-glass:—

Carbonate of potassa, one hundredweight.
Red lead, or litharge, two hundredweight.
Sand—washed and burnt, . . . three hundredweight.
Saltpetre, fourteen to twenty-eight pounds.
Oxide of manganese, four to twelve ounces.
Cullet, or broken glass, *ad libitum*.

Such is the most common proportion; but DUMAS affirms that a finer and more durable product is obtained by reducing the amount of alkali; thus, for three hundred parts of sand and two hundred of minium, ninety to ninety-five parts of purified carbonate of potassa, instead of one hundred, will yield a better result when the furnace draws well—in winter, for example. But in summer, the preceding proportions must be used, or the following French recipe:—

	Parts.
Pure sand,	300
Minium,	215
Purified carbonate of potassa,	110
Nitrate of potassa,	10
Borax,	12

It has been stated, that when open pots are used, as on the Continent, with wood fuel, the proportion of minium may be reduced. This arises from the circumstance, that the oxide of lead, being an active flux, is less necessary for the fusion in uncovered pots, which admit of the direct action of the heat on the contained mixture or metal. However, the use of the three essential ingredients in the ordinary proportion of three, two, and one, is, in all cases, a safe one. It is chiefly for economy that the minium is reduced in amount, when the heating power of the furnace is sufficient to permit the reduction. On the other hand, if the minium be too much reduced, the beauty of the product will suffer. The lowest proportion of this ingredient which can be used with safety is shown in the following composition, which yields a good crystal:—

	Parts.
Sand,	300
Minium,	180
Purified carbonate of potassa,	120
Cullet,	300
Arsenious acid,	0.45
Oxide of manganese,	0.60

The mere due proportioning of the materials for flint-glass is not sufficient—the utmost attention must be given to have them in a state of purity. The silica or sand should be very white, and absolutely free from coloring oxides, as those of iron or manganese. Some manufacturers cleanse the sand by hand-washing, and others have machines. To render the Isle of Wight sand fit for making flint and other compound glasses—that is to say, to cleanse it from chalk and other impurities, by which it loses about one-fifth of its original bulk, requires about eight waters; it is afterwards passed through a heated arch, called a *calker*, and thoroughly dried, or burnt, at the discretion of the operator; and then sifted through a lawn-sieve, to separate the larger grains and pieces of coal or coke. DUMAS recommends that the sands be washed with dilute hydrochloric acid, to remove from them any traces of oxide of iron or of manganese.

The carbonate of potassa also requires a preliminary purification, which is easily effected by dissolving it in water, decanting the quite clear solution, and evaporating the liquor. All the coloring oxides are deposited, and by the evaporation carbonate of potassa is obtained, mixed with other salts, but at least quite free from oxides of iron or of manganese. If the nitrate of potassa were low in price, one might employ it to replace the carbonate.

The protoxide of lead, or litharge of commerce, is almost never pure. It contains oxides of copper, of iron, or of manganese, in too great quantity, in most cases, to admit of its making a colorless flint-glass. Moreover, an oxide of lead is expressly manufactured for the making of crystal. In general, there is selected for this purpose a very pure lead, which is carefully oxidized, to avoid introducing into it foreign and injurious matters. It is the practice to carry the oxidation of the lead to the state of *minium* Pb_3O_4 . Not that the crystal contains red lead; the latter loses by the action of the heat a portion of its oxygen, and passes again to the state of protoxide which alone forms part of the glass. But it is advantageous, and probably even indispensable, to furnish to the mixture which is to produce the flint-glass a body capable of yielding oxygen at the beginning of the fusion.

It has been supposed that this disengagement of oxygen was necessary to produce in the glass the agitation which prevents this product from separating itself in layers of different densities. But DUMAS observes that the decomposition of the minium must be concluded long before the fusion is effected. The oxygen which the minium disengages has very probably, for its object, to burn an organic matter analogous to ulmin,

which is found in large quantity in the crude salt; a matter which is decomposed in part, calcining this last to make potassa of it, but which is still found in the potassas of commerce in notable quantity. This matter, put in contact with the protoxide, would reduce it to the metallic state, and would color the crystal; whereas, being burned by the oxygen of the minium, it disappears, without leaving a trace of its existence.

It is evident that the same result would be arrived at by using nitrate of potassa instead of the carbonate, and that the minium might be replaced by pure litharge, or protoxide of lead. In point of fact, the small quantity of saltpetre which is usually added, exerts a beneficial effect, by increasing the proportion of oxygen, and assisting to drive off the globules of air in the liquid glass. This salt, when the price admits of its application, is at once a pure and a purifying material. A few ounces of manganese are employed to neutralize the greenish tint produced by the presence of iron or other impurities; and, with this view, the peroxide must be used in the purest crystallized state.

Melting and Fining of Flint-Glass.—The plan and sectional elevations of a melting furnace, figured at pages 199 and 200, are equally applicable to flint-glass, and other descriptions of glass, except that for bottle

Fig. 172.

and crown-glass the furnaces are usually oblong, and are only constructed to contain from four to six pots; whereas, for flint-glass works, round furnaces, containing from eight to twelve pots, are almost exclusively used. Mr. APSLEY PELLATT remarks, that ten pots

of thirty-six inches diameter are the medium number for a well-proportioned furnace, and are found the most economical for fuel. When the furnace has too large dimensions, too great an area is left unoccupied by the pots or fuel, and too small a furnace exposes the backs

of the pots to hang over the fire-place in the centre, which in time enlarges by burning away, and causes the pots to crack at the bottom, or back, by cold draughts through the fire-bars. According to the same authority, a furnace of twelve pots, exposing a much larger unoccupied area than a ten-pot furnace, will consume nearly double the quantity of fuel in uselessly heating the interior, whereas twelve pots of melted metal will hold only in the proportion of one-fifth increase. On the other hand, furnaces of less dimensions than eight pots are objectionable, through the great loss of pots, in consequence of the comparatively small size of the siege. In the Falcon glass-house, belonging to Mr. PELLATT—and from which have emanated many important improvements—there are two furnaces, instead of one, both opening into the same flue, as represented in Fig. 172, which shows also an interior view of the glass-house and working operations. By this arrangement, while one of the furnaces is in full operation the other may be undergoing repair, or the working of one may be entirely suspended without injury to the other, during a dullness of trade.

But the principal and only essential difference in the conditions for the melting and fining of flint-glass, consists in the shape of the pots, which, as represented in Fig. 142, page 201, are distinguished from those employed for other descriptions of glass, by being covered with a hood-shaped top, the mouth of which fits the working holes of the furnace, so that the smoke and heat cannot escape in the same way as in the usual glass furnaces. Open pots are used in some parts of France for flint-glass, with dried beech or oak-wood for fuel, and so little carbon is produced by the smoke as not to affect materially the metal, although the flames play upon its surface; but when coal or coke is used, as in this country, the fumes and smoke emitted would carbonize or deoxidize the lead, and precipitate it to the bottom in the original metallic state, if the pots were not covered; besides that the solid particles of soot would blacken the glass, by attaching themselves firmly to its surface.

The ingredients previously mentioned, having been carefully mixed together and sifted, are brought to the furnace in wooden vessels, like hand-barrows, and thrown into the pots in successive charges with an iron shovel. In this state the batch or frit, as the composition is called, is of a salmon color, the red tinge being derived from the oxide of lead. English melting-pots, which are usually much larger than the French, hold about eighteen hundredweight each, and the batch is introduced in quantities of about four hundredweight at a time, allowing a sufficient interval between each filling for melting down the various charges, until the pot is entirely filled with fused glass. By this method, says Mr. PELLATT, every pit in the furnace is fully charged with liquid metal in about twelve to fifteen hours; air-bubbles and striæ then abound, and they are not expelled until thirty to forty hours more have elapsed, during which period—namely, from fifty to sixty hours—the gas and air-bubbles are driven off, and the mass becomes homogeneous. During the founding, the mouths are securely stoppered and clayed up, and the furnace is urged to its utmost intensity. The shorter

the time of fusion and refining, the better; for this purpose the heat can scarcely be too great. With the best possible recipe, and the purest materials, good results depend upon an intense and continuous fusion: too little caloric will fail to refine the metal and drive off air-bubbles, and the coloring matter of the manganese; and too long continuance of intense heat will destroy the manganese, cause the glass to attack the pot, and become striated, gelatinous, and greenish. If the glass do not get fine by the usual time allotted, but becomes coddled or gelatinous, it never will recover, however urged by subsequent fusion. Such glass must be ladled into water, and considered only as cullet for re-fusion, with a proportion of new materials. The moment the metal is fully fused, and refined by continuous rapid fusion, the high temperature of the furnace should be reduced from its maximum heat to a working temperature; this period being considered *the crisis*. When flint-glass is kept in fusion beyond the crisis, it not only assumes a greenish tint by acting upon the iron of the Stourbridge clay-pot, but takes up a small portion of its alumina, which, by its inferior density, rises to the surface, frequently with detached portions of the pot, causing striæ and other impurities, which injure its quality for common uses, and render it entirely unfit for optical purposes. Formerly, scum or sandiver was allowed to run off, or was skimmed from the surface of the pots when opened for working, but the modern relative proportions and purity of the chemical materials are so good, as seldom to render this skimming necessary.—*Pellatt*.

Mechanical Operations.—The mechanical operations connected with common bottle-glass, crown, sheet, and plate-glass, are uniform in their character; the description of the making of one bottle, or of one table, sheet, or plate of glass, applies to all. On the contrary, the infinite variety of shapes into which common flint-glass or crystal is manufactured, would render a complete account of the manipulations tedious, even if it were not in some degree foreign to the plan of this work. Only a few examples will, therefore, be selected, to illustrate the general character of these ingenious processes.

Flint-glass is either formed by simple blowing with the pipe, and then shaping by hand; or, secondly, by blowing in moulds; or, thirdly, by moulds alone, in which the glass is subjected to pressure. In each of these cases, the form and appearance of the article are very generally improved by grinding, cutting, *et cetera*.

By way of illustration, the common tumbler may be mentioned as one of the simplest articles to make by hand.

In this case the workman collects on the end of the pipe a small quantity of glass—Fig. 173; this is rounded on the marver, expanded by blowing, and somewhat elongated by swinging, when it assumes the form—Fig. 174. The pipe is then suspended vertically, and the glass is allowed to drop by its own weight upon the marver, which flattens it at the extremity; and, being at the same time further

Fig. 173.

Fig. 174.

blown, it now resembles—Fig. 175. The pipe, with a

Fig. 175.

Fig. 176.

Fig. 177.

Fig. 176—so as to make it perfectly even, as at D—Fig. 177—and fit it for the flashing and finishing. Finally, it is knocked off from the ponty by a sharp blow, and taken to the annealing arch.

Part of the above process is omitted for common light cheap tumblers; these are not sheared, but simply flashed, and no pains is taken in subsequently polishing out the marver marks. Hence they are often ringy or wavy.

Wine-glasses are usually made in three pieces. The process is the same as for the tumbler, till the gathering assumes the shape represented in Fig. 175. A solid ball of glass is then attached to the flat end, as in Fig. 178, this being a separate gathering, out of

Fig. 178.

Fig. 179.

Fig. 180.

Fig. 181.

which the stem is shaped by the pucellas, while it is rotated on the inclined planes of the glass-maker's chair. It then assumes the form represented in Fig. 179. To form the foot, a small hollow globe is now attached to the stem, which is afterwards opened by the pucellas, as in Fig. 180; and when the pipe, with a portion of the glass, is separated from the other end, and the mouth expanded, sheared, and flashed, the glass finally assumes the form represented in Fig. 181.

To make a ringed decanter, the glass, by the process already described, is brought to the form represented in Fig. 182. The ponty is then attached to the flat end,

and the mouth is warmed up, and shaped with the pucellas, as in Fig. 183. Another workman then gathers upon a ponty a small piece of glass, which is dropped on near the mouth, as shown in the same figure, and, by rotating the decanter, the entire circle or ring is welded by contact, and its surplus tapered and torn suddenly off. By re-heating the

Fig. 182.

Fig. 183.

decanter, a second, third, and fourth ring may be added, as shown in Fig. 184.

The process of blowing and moulding common green glass bottles has been briefly described at page 210. Bottles and other articles of flint-glass are blown and moulded in much the same manner, but the finer descriptions are afterwards cut and ground. Moulded glass never exhibits a full lustre, nor even the sharpness of the metallic mould. The glass, not being perfectly liquid, does not penetrate into the sharp corners, nor does it even accommodate itself perfectly to the flat sides of the mould. Hence the edges are blunt, and the surface is never perfectly even, but more or less curved and wavy. Moulded articles can, therefore, never be compared with cut-glass, but some are now produced of remarkable beauty; and even as a preparatory step to grinding, the use of moulds is of great advantage, as the vessel acquires a regular form, and presents, although in a crude state, all the prominent and receding features, to be perfected at the lathe.

The moulds for flint-glass are carefully constructed of brass or iron, and, when of simple construction, are somewhat wider at the upper part, that the pieces may be easily removed, or are composed of more than one piece when projecting parts are to be moulded. A common *open and shut mould*, such as is used for apothecaries' phials, as well as for common wine-bottles, is shown in Fig. 185. It is constructed in two exact

Fig. 185.

halves, connected with a bottom hinge. The glass to be moulded is gathered on the pipe, rolled on the marver into a cylindrical form, and then pinched with

the pucellas at the end attached to the pipe, to form the neck of the bottle. The cylindrical mass, still adhering to the pipe, is then inserted into the mould lying on the ground; its two halves are shut; and the workman blows through the tube, which renders the mass of glass hollow, while it receives from the mould the external form required. With this form of mould two seams or lines are produced, by the two sides of the mould not shutting quite closely. In round bottles these seams are unsightly, but they are scarcely perceptible in square bottles, as the joinings of the mould are placed at two of the corners.

This imperfection, though not entirely removed, is much diminished by the use of an improved mould, invented by Mr. PELLATT, and represented in Fig. 186. It consists of one piece, D, for the body, and two pieces, B B, for the neck. By this construction the seam down the body, so objectionable in round bottles,

Fig. 186.

is avoided, although the neck is still marked by two slight seams. The neck-pieces, which are kept open by a spring, C, are brought together, after the insertion of the globe or spheroid of metal, by the guide, E, on pressing down the treadle, F, with the foot. The workman then blows through the pipes, and, on raising his foot, the counterweight, A, falls, and the bottle is readily taken out.

Moulded Roman Pillars.—With reference to this species of moulding, recently introduced by the English manufacturers, Mr. PELLATT remarks that it owes its refractive and cut-like effect to its inequalities of substance, the interior having no indentations to correspond with its exterior projections. In this case the mould is only about one-third the size of the object to be manufactured. The metal is first gathered upon a pipe in the ordinary manner, except that the first gathering is allowed to cool more than

Fig. 187.

Fig. 188.

usual, and the second coating is pressed into the mould, A—Fig. 187—as hot as possible, so that only the exterior portion may be acted on by the mould, while the

interior preserves its smooth circular section. When about half-formed, the projecting parts, B—Fig. 188—have a centrifugal enlargement given to them by a sharp trundling of the iron at, or immediately after the blowing. During the re-heating process, the piece is separated at the dotted line, C, has a foot welded to it, and is rewarmed as D—Fig. 189. It is then sheared, as E—Fig. 190; and when finished by flashing, shaping,

Fig. 189.

Fig. 190.

et cetera, so as to appear as in Fig. 191, it is known as patent pillar moulding. A little cutting or scolloping makes this refractive moulding still more ornamental; but though it much resembles cutting, as to its round pillars, it is inferior where sharp angles are required. Pillar moulding is, however, one of the greatest modern improvements, and is used advantageously for lamp-pedestals, chandelier work, toilet-bottles, salt-cellar, *et cetera*, at very moderate cost.—*Pellatt*.

Fig. 191.

It may here be remarked that all bottle-moulds require, while working, to be kept nearly at a red heat, either by a small furnace, or by a piece of hot glass held inside by a boy on the end of a ponty-rod during the intervals of the moulding. This precaution is essential to the polish, but the heat of the moulds must be kept below redness, otherwise the glass would adhere to them.

Pressing.—The third method of manipulation with flint-glass, is moulding by pressure—an American invention, which consists in dropping the soft metal into a prepared die, and then pressing down the matrix or plunger upon it by means of a lever. The chief conditions of success in this operation are, to take care that sufficient glass is introduced to fill the mould, and that the latter is kept at a steady temperature, a little short of red heat, to produce a polished surface. When the die or mould is once formed, articles are produced in this way with great rapidity; but much practice and dexterity are required to gather the exact quantity of metal. Under this head may be mentioned

Fig. 192.

drop-pinching, or the moulding of drops for chandeliers, girandoles, and candlesticks. In this case, lumps of glass made expressly for the purpose, are first softened by a blast-furnace, and then shaped in twin-dies, A B—Fig. 192. Arms of chandeliers are formed

on the same principle, but using a powerful leverage press. Both arms and drops are afterwards cut and polished, to produce the required brilliancy.

Cutting and Polishing.—The finishing process which gives to the finer articles manufactured of flint-glass their distinguishing beauty, is technically termed *cutting*, but is actually performed by grinding. The inferior hardness of flint-glass renders it fitter for this purpose than any other glass. The operation, as represented in Fig. 193, is performed by discs of iron, sandstone, or copper, revolving in a lathe which is

usually propelled by steam power. The edges of the discs, which are sharp, angular, or rounded, according to the work to be performed, are supplied with sand and water dropping from a hopper for *rough grinding*, and with emery for *fine grinding*. A stone-wheel with water is employed to smooth out the rough sand-marks, and prepares the glass for the *polishing*, which is effected by means of a willow-wood disc, first with a mixture of pumice and rotten-stone, and finishing with a preparation of tin and lead, termed putty-powder. All table-glass ware and hollow articles are thus cut.

Fig. 193.

Chandelier drops are cut or ground with iron and stone-wheels in the same manner, but are finished with a lead-wheel supplied with a little very fine rotten-stone and water.

For many years the practice has been introduced of roughing lamp-lustres by means of sand. It is easy to conceive how the exterior roughing may be performed, but the rubbing of the interior surface appears a more difficult operation. It is, in fact, performed on a somewhat different principle. In this case, sand of a uniform grain is put into the globe or lustre; a certain number of these globes are arranged in a drum or cylinder, and a rapid rotatory movement is given to the latter, by means of which the interior surfaces of all the globes are quickly worn and roughed in a very equal manner.

Glass-Engraving.—Small copper discs of the size of

a halfpenny, and finely pulverized emery mixed with oil, are used to execute the outline and ground of the glass-engraver's work; and for polishing, lead-wheels and very finely pulverized emery are employed. Coarse patterns for hall-lamps are engraved by the glass-cutter's smoothing wheel; and Mr. PELLATT remarks that the contrast of the polish of a wood-wheel upon a ground roughed by sand is often effective, though the range of pattern is somewhat curtailed by the large size of the cutter's ordinary wheels rendering it difficult to execute curvilinear designs. For inscribing initials, coats of arms, and minute designs, very small discs must be employed. The finest incisions are made with copper pencils, either pointed, or ending in a button-like disc.

Etching on Glass.—It has been stated at page 199, that hydrofluoric acid, either in the gaseous or liquid

state, exerts a peculiar action on glass, which has been turned to account as a substitute for cutting or engraving designs; and though not confined in its application to flint-glass, the process may be appropriately described in this place.

For etching on glass by means of the gaseous acid, the glass is cleaned, well dried, heated, and melted varnish poured upon it, which is spread in a homogeneous coating. This varnish is formed of wax and turpentine; it ought to be soft enough to admit of being removed by the burin without scaling it off; it is generally formed of one part of turpentine to four parts of wax. When the glass is cold, the varnish acquires a little opacity, but not so much as to prevent tracing through it. The burin is then passed over the varnish, following the lines of the figure, and cutting through the varnish to the glass. When the figure is traced, the glass so prepared is exposed to the action of hydrofluoric acid. For this purpose a leaden tray or earthen vessel is used; in this is put fluoride of calcium pulverized with concentrated sulphuric acid; it is mixed well, and the vessel is then placed on a very gentle fire, and the glass to be etched is laid over it. At the end of some minutes from the time when the vapor begins to rise, the operation is terminated; the glass is then taken off, and the varnish is removed by melting it, and wiping with a soft linen rag.

If, instead of exposing the glass to the action of the acid vapors, it is plunged into the weak liquid acid, the same effect is produced in a few moments.

But when it is desired to produce a very pure and correct figure, with half-tints and strong shades, recourse must be had to a longer and more delicate process; a particular varnish, too, must be used.

The best is drying linseed oil, or, better still, fat varnish of copal blackened with lamp black, perfectly pulverized, and sprinkled with oil of turpentine. The coatings laid on must be very thin, and each should be quite dry before putting on a new one. The glass is sufficiently covered with varnish when the light can scarcely be seen to pass through it. The design is then copied through, and the varnish is removed from the lines with the points of gravers, or simple needles of different forms and sizes. For greater convenience, the design is lighted from below by inclining it at an angle of about 45° on a desk pierced for a window. The position of the glass enables one to perceive the most delicate lines.

After having formed the figure, it must be corroded out with liquid hydrofluoric acid; but before commencing this operation, it is necessary to test the glass as well as the acid. This preliminary trial is made on a small piece of the same glass, covered with the same varnish. This piece is divided into five or six parts; on each of these parts some traces are drawn with the needle, and the operator covers them successively by means of a pencil with liquid hydrofluoric acid. A minute is allowed to intervene between each operation, so that when the acid has acted during one minute on the last portion, it has then been in contact with the glass for two minutes on the preceding one, and for six minutes on the first. This being done, the slip of glass is washed with plenty of water, and the varnish is re-

moved by means of a knife and spirits of turpentine. It is then easy to determine the proper time for allowing the acid to act upon the design to be etched.

BEDFORD patented a peculiar process for etching glass, which consists in grinding five parts of peroxide of lead and one part of flux, composed of seventeen parts glass of borax, and thirteen parts of red lead, fused together. The peroxide of lead employed is puce-colored, and with the above composition the artist paints the devices or designs upon the surface of the glass. When the etching is to be done on colored glass, acetate of lead is substituted for the oxide. The article is then dried, and fixed in the same manner as in gilding glass. When cold, it is dipped in a weak solution of nitric acid, and as soon as the painted designs are acted on, it is placed in water, and the preparation removed from its surface.

On the whole, it must be admitted that etching by fluoric acid, though practised to some extent, and in some particular cases with marked success, has not been found effective for general purposes. It is usefully applied, however, to form the scales on thermometer tubes, and written or printed inscriptions on glass vessels. The attempt to make it subservient to topographical purposes has been a failure.

OPTICAL GLASS.—There are two kinds of optical glass—flint and crown—which, having different refractive and dispersive powers, may be so combined in the object-glass of a telescope that, while the rays are brought to a focus, the greater dispersion of the flint lens may be corrected by the less dispersive power of the crown—the one being negative, the other positive. Hence, by their combination, the lenses achromatize each other, or transmit colorless light. The celebrated DOLLOND, in 1753, aided by the co-operation of EULER, and of KLINGENSTIERNA the Swedish mathematician, succeeded, after many experiments, in discovering the due proportions of the curvatures of the two lenses; but still two important problems remained to be solved—the best chemical constitution of the glasses, and how to obtain them sufficiently free from the defects of ordinary glass to be adapted for optical instruments. It is this last question which presents the greatest difficulty. Purity, unchangeableness of color, transparency, and a certain degree of refractive power, may be obtained; but perfect uniformity in the structure of the glass, so as to render its composition absolutely homogeneous throughout, is much more difficult to be accomplished; and this is precisely the quality which is admitted to be the most indispensable for good optical glass. The difficulty arises chiefly from the difference in specific gravity of the different constituents of the metal. Some melt at a lower temperature than others; some evaporate or are decomposed in a heat required for the fusion of others; and different substances cool at different temperatures. Hence arise discoloration, threads, striæ, irregular crystallization, causing irregular refraction, and all the usual faults observable, more or less, in every description of glass.

It seems to be now generally admitted that there are more impediments in fabricating crown-glass lenses of large size, than in making good ones of crystal or flint-glass. The former requires a higher temperature, and

by adding alkali to increase the facility of fusion, it becomes more liable to attract humidity, or, as it is technically termed, to sweat. On the other hand, by rendering it too hard, one incurs the risk of crystallization and imperfect vitrification in cooling.

For a long period, however, the principal attention of opticians and glass-makers was devoted to the manufacture of a suitable flint-glass, which was considered to present the greater difficulty of the two. Occasionally, the flint-glass manufacturers found in their pots a portion of glass suitable for opticians; but this was an accidental product. The problem of the constant and regular manufacture of good optical flint-glass still remained to be solved, when M. GUINAND, a workman in the clock and watch trade, near Neufchatel, who had been accustomed to the fusing of metals in the prosecution of his business, devoted his attention to the subject, and succeeded in producing masses of flint-glass capable of furnishing objectives of nine inches—a size previously unknown. Even the celebrated chemists, MACQUER ROUX of St. Gobain, and AUUT of Langres, had never been able to obtain them of larger diameter than three to three and a half inches. M. DARTIGUES also, one of the first manufacturers of flint-glass in France, and who to his high reputation for practical skill added that of scientific knowledge, equally failed of success. GUINAND's discovery was therefore hailed with much satisfaction; but he kept the process a secret, except from M. UTZSCHNEIDER and the celebrated M. FRAUENHOFER, who proposed to him to join them in their establishment at Munich. This offer GUINAND accepted, and the process was successfully worked by them for several years without any one being able to discover it. After their deaths, one of GUINAND's sons being in possession of his father's method, continued the manufacture of optical glass in the environs of Neufchatel. The other son formed an association with M. BONTEMPS, one of the directors of the glass-work of Choisy-le-Roi, but the experiments which were made by them conjointly at that establishment did not succeed. The treaty was therefore broken; but M. BONTEMPS and his co-director, M. THIBEAUDAU, satisfied of the correctness of the principle, if properly applied, continued their experiments without excluding GUINAND; and ultimately, in 1828, they succeeded in producing good optical glass in discs of from twelve to fourteen inches, and a large quantity of smaller sizes. From that time the manufacture has been established on a regular system. In 1848, M. BONTEMPS was induced, in consequence of difficulties arising from the political state of the country, to retire from his position at Choisy-le-Roi, and to accept the invitation of Messrs. CHANCE, Brothers, and Company, to unite with them in attempting to improve the quality of this important branch of manufacture. How far they have succeeded may be judged of from the fact, that they have produced discs of flint-glass twenty-nine inches in diameter, weighing two hundredweight, and of crown-glass up to twenty inches. These discs are pure in color, good in structure, and exempt from those defects which tend to polarization of light. BONTEMPS' proportions for optical glass are as follow:—

FOR FLINT-GLASS.

Sand,	43.5
Red lead,	43.5
Carbonate of potassa,	10.0
Nitrate of potassa,	3.0
	<hr/>
	100.0

FOR CROWN-GLASS.

Sand,	60
Carbonate of soda,	25
Carbonate of lime,	14
Arsenic,	1
	<hr/>
	100

It will be observed that optical flint-glass is chiefly distinguished by the large proportion of lead which enters into its composition. According to DUMAS, who approached very near to the truth in assigning its probable composition, its density should not be lower than 3.6 at least. The essential point in the manufacture, however, consists in the constant stirring of the metal during the melting and fusing. The superiority of GUINAND's plan is considered not to have been in the novelty of the materials or proportions, but in carefully agitating the liquid glass while at the highest point of fusion, then cooling down the entire contents of the pot in a mass, and, when annealed and cool, separating unstriated portions by cleavage. It is worthy of remark, that some time before GUINAND's death, a commission of the Astronomical Society of London, composed of Messrs. HERSCHEL, FARADAY, DOLLOND, and ROGET, having been instructed to conduct an inquiry into the manufacture of flint-glass for optical purposes, arrived at the result that the necessary improvement was chiefly mechanical, not chemical, and that freedom from striæ could only be obtained by a constant agitation of the mixture. FARADAY, who took the lead in the inquiry, both in his own laboratory and at the glass-works of Messrs. PELLATT, changed, however, the composition, as well as the principle of fabrication, and produced a borate of lead of remarkable purity. This substance, known as FARADAY's heavy glass, which has proved so important in experiments connected with the polarization of light by magnetic action, is composed of the following ingredients:—

Protoxide of lead,	104
Silicate of lead,	24
Dry boracic acid,	25

This glass required but a red heat for fusion, thereby, as Mr. PELLATT remarks, offering facilities for minute agitating operations. It was found, however, not to be durable, and therefore not calculated for application to optical purposes or general use. The common process for making optical glass is described by Mr. PELLATT as follows:—A ladle, in the form of a sugar-loaf, about five inches in diameter and seven inches deep, is dipped carefully into the metal, which has been previously skimmed; when filled, it is taken out of the pot, and suffered to get partially cool. To the large end of the sugar-loaf-shaped piece of glass thus produced, a glass-blowing iron with a hollow disc is welded, and placed to the opening or mouth of the pot for reheating; when sufficiently soft, it is blown into a muff; the end furthest from the blowing-iron is cut off, the cylinder is flattened into pieces or plates of fourteen inches long, ten inches wide, and about half an inch thick, and annealed; in

which state the plates are sold to the optician for cutting and grinding into discs.

Zinc Optical Glass.—Allusion has already been made to a new kind of glass which was sent to the Great Exhibition of 1851 by M. MAËS of France, and was honored with a Council medal, as an instance of novelty of chemical application in the manufacture of optical and other descriptions of glass. The basis of this vitreous compound was oxide of zinc—a certain quantity of borax or boracic acid being added, to give the glossy character for which the boracic compounds, no less than the silica, are so eminently remarkable, combined with an easier fusibility. Its extreme limpidity, and total freedom from color, veins, and striæ, appeared to the council jury eminently to fit it for telescopes, prisms, and other optical apparatus—as a substitute, however, not for the flint-glass, but for the crown, in achromatic telescopes. The low dispersive power of the zinc compounds points to the use of glass of zinc for this purpose. Its refractive index is 3.285, and its dispersive ratio, as compared with a flint-glass of specific gravity 3.55, is as 0.6502 to unity. With reference to this peculiar glass, the following passage occurs in the Report of the Council Jury on Optical Glasses:—Suppose it should be found practicable—and the experiment is recommended to the attention of artists, as one in which, when tried on a very small scale, some success has actually been obtained—to form colorless and uniform glasses, in which fluorine enters as a distinguishing ingredient, in combination with silica, alumina, or other materials; the combination of such glass, as a convex lens, with this new material of M. MAËS, or with ordinary crown-glass as a concave, might be expected to produce achromatic object-glasses of a very perfect description. The colored dispersion to be removed being much less than that of crown-glass, owing to the peculiarity of the fluoric compounds which beset the manufacture of flint-glass, arising from the intense solvent power of the oxide of lead on the crucibles, and give rise to striæ and veins, would be evaded. M. MAËS, besides two prisms of his new glass, of the most limpid purity, and perfect freedom from veins or striæ, exhibited two discs of four and a half and seven inches in diameter, prepared for optical use. In an examination, through faces cut on their edges, no veins or striæ were detected, and, consequently, should there arise no objection to this material, either in point of durability or facility of working, it will probably prove very valuable for the use of the optician.

VI. STRASS AND COLORED GLASS.—The manufacture of glasses tinged, colored, or stained, by different processes, has now become a business of great and growing importance. The taste for stained-glass windows, which formed so distinguished a feature in the history of a former period, has revived, and is now displayed in the decoration, not only of splendid palatial and ecclesiastical structures, but even of many private dwellings; the skill of the Venetians of a former day, in producing colored vases and other ornamental articles of glass of every variety of hue, is equalled if not surpassed in modern times; and artificial gems, or pastes, which are true glasses, are now formed, that emulate,

if they do not eclipse, in sparkling lustre and pure transparency, the rarest and most beautiful natural productions of the mineral kingdom.

Although all the varieties of glass can be colored at pleasure by virtue of the property possessed by the greater number of the heavy metallic oxides of producing colored compounds with silica, yet in individual cases it depends upon the object in view, and even on the nature of the color, whether a glass void of lead, or a lead-glass with its higher refractive power, is employed as the basis for the coloring material. In general, however, the basis of the color, or that with which the coloring matter is actually mixed, is a lead-glass, and this, when real *glass-painting* is the object, is applied either as a pigment or in a melted state on common glass or some other finished article; in other cases, the colored lead-glass is itself formed, cut, or moulded into the finished article. When the latter is an artificial gem or paste, a peculiar glass is employed, termed *strass*, which it may be proper to describe in this place, before proceeding to give a short account of the different coloring materials, and the different methods of their application in particular cases.

Strass, so called from the name of its inventor, constitutes the only true glass not yet described, and forms, as above stated, the basis of artificial imitations of precious stones. For this purpose a glass is required, possessing the highest degree of purity and transparency, combined with the greatest possible lustre. These requirements are found in a composition analogous to that of flint-glass, but containing a much larger proportion of oxide of lead and a little boracic acid. DONAULT-WIELAND recommended, by way of example, either of the three following mixtures:—

	No. 1.	No. 2.	No. 3.
Ground rock-crystal,.....	100	—	100
Sand,.....	—	100	—
Pure minium,.....	156	—	154
White-lead,.....	—	171	—
Purified caustic potassa,.....	54	32	56
Boracic acid,.....	7	9	6
Arsenious acid,.....	.3	.3	.16

From these proportions, and from the analysis of a strass manufactured by DONAULT-WIELAND, which was given at page 192, it will be seen, that not only does the oxide of lead greatly exceed in amount that which is contained in crystal or common flint-glass, but that it is present in larger proportion than even in optical flint-glass. This will be observed by glancing at the same table in the page above-referred to, where flint-glass from GUINAND, or, in other words, optical glass, is placed in juxtaposition with strass and enamel. The very large proportion of oxide constitutes, in fact, the distinguishing peculiarity of the former, while the latter is further distinguished by containing oxide of tin, or is in reality a strass with a mixture of oxide of tin or stannic acid.

Strass, when well prepared, possesses as nearly as possible the high refractive power and all the other properties of the diamond, except its hardness. When cut into shape, therefore, without the addition of any coloring matter to its composition, it answers for imitating the diamond. On the contrary, when tinged by

silicates with metallic bases, it furnishes imitations of all the colored stones. For this purpose its perfect purity and high lustre are essential requisites. It is necessary, therefore, to exercise great care in the choice of the materials. The rock-crystal, quartz, or sand employed, must be of the purest description. The last two always contain a little iron, which colors the glass yellow, and should therefore be washed with hydrochloric acid after being carefully pulverized. The potassa must not be mixed with any other salts. DONAULT-WIELAND preferred the finest caustic potassa; but DUMAS remarks that the use of the nitrate might be preferable on account of the constant purity of that salt. The borax of commerce—that of Holland, for example—would produce a brown glass; crystallized boracic acid is therefore preferred. The oxide of lead employed is very pure minium.

DUMAS remarks that the choice of the crucibles is very important, and that the Hessian ones are better than those of porcelain. The crucibles sometimes color the metal yellow or brown, when particles of iron are detached from the internal surface. This inconvenience is not to be apprehended with crucibles of hard porcelain, but these often break or run out, and are too permeable. A pottery or porcelain furnace is used to melt the material, and the crucibles remain in the fire about twenty-four hours. The more tranquil and prolonged the fusion, the greater hardness and beauty does the strass acquire. If the crucibles are of excellent quality, a porcelain furnace may be used; but when the loss occurring is too great, one must be contented with a common potter's furnace.

COLORING MATERIALS.—It has been stated that colorless strass is the basis of artificial gems, most of which are formed by mixing with the strass certain coloring materials. In the article ENAMELS, many of the substances employed for this purpose have been enumerated; but further details may now be given in connection with the general subject of *colored glass*, before proceeding to the special proportions employed for imitating certain precious stones.

Yellow is produced either by charcoal, antimony, silver, or oxide of uranium. The charcoal, incorporated with the glass in a very fine state of division, produces a dirty yellow, which, as the quantity increases, passes into a dark brown without lustre; it is, therefore, little used as a pigment. A much superior yellow is obtained by roasting sulphide of antimony to the state of antimonious acid, and melting it with from 3 to 5 per cent. of undecomposed sulphide of antimony. An *orange yellow* is prepared with glass of antimony, minium, and a little oxide of iron. In these cases, the substances so prepared are mixed with the materials of the glass. When silver is employed, the process is quite different; in this case a mixture of powdered clay and chloride of silver is applied to the surface of the ready-made articles, and on reheating these in a muffle, the silver penetrates to a certain depth into the glass even before the latter softens; the article is then allowed to cool, and the coating which was applied is scraped off, when a yellow color of great purity and brilliancy appears on the glass. It is remarkable that this effect can only be produced on glass containing alumina, which shows

that the action is chemical, and not purely mechanical. Oxide of uranium produces a beautifully delicate yellow of a slightly greenish hue, which is attributed to the traces of iron usually found in the commercial oxide; but this pigment is too costly for common use.

Red, of different shades, is communicated by oxide of iron, suboxide of copper, or different preparations of gold, mixed with other materials. The oxide of iron— Fe_2O_3 —is employed either as pure oxide, prepared by heating the nitrate, or in the state of bloodstone or ochre. This substance, added to the glass mixture, produces a cheap and very common brownish red. The peculiar action of suboxide of copper has already been explained under ENAMELS, vol. i. page 821. This substance was much employed by the artists of the fifteenth and sixteenth centuries, for producing the brilliant red colors of window panes, and in later times the glass so colored was supposed to be indebted to gold for its beautiful rich hue. So intense is the coloring power of this oxide, that even a very small quantity reddens the glass so much as to render it opaque, and hence it is almost impossible to command any desired tint in applying it. Even a common window pane is scarcely permeable to the light when coloured with a small portion of this substance; and hence in crystal vessels, which are necessarily of much greater thickness, especially when intended for grinding, the effect becomes excessive—the glass is rendered quite opaque. To obviate this difficulty, recourse is had to the process of *flashing* or coating white with colored glass, as will be explained afterwards—a process so successful that it was subsequently extended to other colors.

The application of gold to produce a brilliant red color, which, according to circumstances, can be made to assume a scarlet, carmine, rose, or ruby tint, was first introduced by KUNKEL, who used for the purpose the brownish-red precipitate produced in a solution of chloride of gold by a salt of the sesquioxide of tin. This substance, known as the purple of CASSIUS, was long believed to be the only preparation of gold which could be employed for this purpose, till FUSSE demonstrated that ruby-colored glass may be obtained when the powdered ingredients for the glass are mixed, previous to fusion, with oxide of tin and the solution of gold; the mixture then appears like moist grey sand. Experience has further shown that the simple addition of a solution of gold to the flux, without any oxide of tin, is capable of producing rose and carmine-colored glass.

Blue is produced by oxide of cobalt, a pigment which is equally applicable to lead-glass and to glass containing no lead, but in the latter the color is more intense. The coloring power of the oxide of cobalt is so intense, that pure white glass is rendered sensibly blue by the addition of one-thousandth part of the oxide. Ample information as to the methods of preparing blue cobalt glass, which is produced in a pulverized state as a pigment, under the name of *smalt* or *zaffre*, has been given in the article COBALT.

Green may be produced either by protoxide of iron, protoxide of copper— CuO —or oxide of chromium— Cr_2O_3 . The tint produced by the first of these substances has little brilliancy. The oxide of copper yields

a beautiful emerald. For this purpose the glass is mixed with the product obtained by heating copper to redness with access of air, or with powdered verdigris, which is then decomposed in the fire, and converted into oxide by oxidizing agents. Care must be taken to prevent the protoxide of iron from being converted into sesquioxide, and the oxide of copper from being reduced to suboxide. The oxide of chromium, which occurs as a pigment in commerce, yields the purest and most brilliant grass-green hue, but is too costly for common use.

ARTIFICIAL GEMS.—The preceding cases may be sufficient to illustrate the general character of the substances employed to tinge glass, whether in the fabrication of artificial gems, or in the more important art of enriching with color articles of common use or ornament. Before proceeding to this latter subject, which embraces different methods of applying the coloring material, the following may be given as the most approved recipes for imitating those precious stones that are deemed of highest value:—

Diamond.—Colorless strass, without any addition.

Topaz.—DONALD recommends the following mixture:—

Very white strass,	1000
Clear yellowish orange-red glass of antimony, ..	40
Purple of Cassius,	1

A very good imitation of topaz is obtained from—

Strass,	1000
Oxide of iron,	10

Topaz, when obtained by the first of these two compositions is very subject to vary in tint during the fusion, according to the temperature and the time it is exposed to the fire. It passes from the colorless strass-white to a sulphur-yellow, violet, and reddish purple, according to circumstances, which are not well understood. This substance may be compared to the *rubin-glass* of the Germans and Italians. The glass of antimony must be selected of the greatest transparency, and of a clear orange-red yellow.

Ruby.—This is the rarest and most highly prized of artificial stones. The preparation of topaz furnishes a means of obtaining constantly and at pleasure very fine rubies. The mixture for topaz often gives an opaque mass translucent at the edges, and presenting in its thin plates a color red by transparency. One part of this opaque topaz-matter, and eight parts of strass melted in a Hessian crucible, when left thirty hours in the fire of a potter's furnace, give a fine yellowish crystal similar to strass. Remelted with the blowpipe, this produces rubies of the finest water.

A ruby not so fine, and of a different tint, may be made by employing the following proportions:—

Colorless strass,	1000
Oxide of manganese,	25

Emerald.—The emerald is very easy to imitate. That which succeeds best results from the mixture of the oxide of copper with colorless strass. If oxide of cobalt be added, the green obtained presents blue reflexions. The composition which gives the best imitation of natural emerald is as follows:—

Colorless strass,	1000
Pure oxide of copper,	8
Oxide of chromium,	0.2

By increasing the proportion of chromium or oxide of copper, and adding oxide of iron to the mixture, one may vary the green shade, and imitate peridot or dark emerald.

Sapphire.—To produce a fine oriental blue color, one must employ very white strass, and very pure oxide of cobalt. This composition, put into a luted Hessian crucible, should remain thirty hours in the fire. The proportions are as follow:—

Colorless strass,	1000
Oxide of cobalt,	15

Amethyst.—The color of this stone must be fine and velvety, to be of any value. The formula which succeeds best is the following:—

Colorless strass,	1000
Oxide of manganese,	8
Oxide of cobalt,	5
Purple of cassius,	0.2

Aqua-marina is a gem in little request—even the real stone. As generally met with, it is of a pale emerald tint, but the most valuable kind is colorless like the diamond. The colored kind is obtained by mixing—

Colorless strass,	1000
Glass of antimony,	7
Oxide of cobalt,	0.4

Syrian Garnet.—This stone, which was anciently termed *carbuncle*, has a lively color, for which it is much esteemed. It is especially employed for small jewels. The artificial garnet is a kind of dark ruby, and is made after the following formula:—

Colorless strass,	1000
Glass of antimony,	500
Purple of cassius,	4
Oxide of manganese,	4

In the fabrication of artificial stones, there are many precautions to be taken, many points to be observed, which can only be acquired by experience. The materials must be pulverized with great care. The mixtures can only be well made by repeated sifting. The same sieve must not be used for sifting different compositions, whatever care be taken to clean it after each operation. Lastly, to obtain masses well melted, quite homogeneous, without striæ or bubbles, it is necessary to employ substances very pure, and mixed in a state of extreme division; to obtain the best crucibles, to melt with a graduated heat, in a furnace which is quite equal in its maximum temperature; to leave the metal in the furnace during twenty-four to thirty hours, and to cool the crucibles very slowly, that their contents may undergo a kind of annealing.

COLORED FLINT-GLASS.—Assuming as the composition of the glass to be colored the common ingredients and proportions quoted at page 230, and remembering that these materials, when mixed together, are technically termed *batch*, and, when fused with the usual precautions, produce a highly pellucid flint-glass, this may be regarded as the basis of the following colored glasses, given on Mr. PELLATT's authority:—

Soft White Enamel.—To six hundredweight of batch

add twenty-four pounds of arsenic, six pounds of antimony.

Hard White Enamel.—To six hundredweight of batch add two hundred pounds of putty prepared from tin and lead.

Blue Transparent Glass.—Six hundredweight of batch colored with two pounds of oxide of cobalt.

Azure Blue.—Six hundredweight of batch with about six pounds of oxide of copper.

Ruby Red.—Six hundredweight of batch with about four ounces of oxide of gold.

Amethyst or Purple.—Six hundredweight of batch with about twenty pounds of oxide of manganese.

Common Orange.—To six hundredweight of batch add twelve pounds of iron ore and four pounds of manganese.

Emerald Green.—To six hundredweight of batch add twelve pounds of copper scales and twelve pounds of iron ore.

Gold Topaz Color.—Six hundredweight of batch with three pounds of oxide of uranium.

FLASHING AND CASING.—In speaking of the sub-oxide of copper, it has been stated that the coloring power of this substance is so intense that even a very small quantity of it renders the glass opaque; and allusion was made on that occasion to the process of *flashing*, by which the difficulty is overcome, and which, on account of the facilities it affords for regulating the intensity of the tint, has been extended to the manufacture of articles of every variety of hue. This process consists in coating a layer of colorless, with one of colored glass, which can then be reduced, by grinding, to the proper tint. For this purpose the glass-blower collects the proper quantity of colorless glass on the end of his pipe, rolls it upon the marver, and then dips it for a moment into a pot of melted colored glass, and blows out the two together into a cylinder or globe, which is flatted or *flashed* out in the usual way. In this manner panes for the glass-painter are formed, which consist of two layers of glass, one colored, the other colorless; and the former can be ground down to any required tint or degree of transparency. An ingenious application of this process is made to vessels of flint-glass, which are tinged on the outside in a similar manner, and colorless edges or facets are then produced by cutting through the outer layer of colored glass, into the substratum of pure white glass.

Flint-crystal glass is usually colored by a somewhat similar process termed *casing*, and thus described by Mr. PELLATT. Presuming that any two or more glasses intended for casing have been mixed of the same specific gravity, to give them the capability of harmonizing—that is, of contracting and expanding equally—the blower has to gather a ball of solid glass, intended for the interior layer, in the usual manner, as A, Fig. 194, which, in this instance, may be considered to be of white crystal glass. About the same time his assistant prepares a casing of colored glass, B, knocking off the knob at c, to open and shape it, as D, somewhat like the bowl of a wine-glass, or the broad end of a large egg-shell; this is set into a metal stand, E, on the floor, merely to steady the case or shell, D'; while the blower takes the lump of flint or white glass, A, and

gently blows it into the colored case or shell, D', to which it immediately adheres; and when submitted to

Fig. 194.

the flame of a pot-hole, it is found to weld perfectly, as F. If various coverings are needed, as many colored shells must be prepared as required, and each time melted in by fresh warming, until the entire number are obtained and cased. The whole are afterwards rewarmed, expanded, and shaped into vases, tazzas, or such other articles as the manufacturer requires, by blowing, and the usual appliances of moulds, tools, rotatory motion, *et cetera*. When cut through to the crystal in various figures, the edges of the different colors on enamel are seen.

In connection with *flashing* and *casing*, may be mentioned a variety of methods of producing colored or variegated or ornamental glass, some of which are very ingenious, and are chiefly derived from the Venetians.

Venetian filigree work is produced in the following manner:—Pieces of *cane*, or solid rods of glass, of different colors, having been drawn out in the same manner as tubes, and whetted off to the required lengths, are arranged in the flutes or internal grooves of a cylindrical mould, A, Fig. 195. The blower then inserts a solid ball of transparent flint-glass, B, Fig. 196, and the whole is exposed to a welding heat, till the

Fig. 195.

Fig. 196.

Fig. 197.

canes adhere to the ball. Both are then withdrawn with it from the mould, when the piece presents the appearance represented in Fig. 197. When again heated, drawn, and twisted, the streaks of color produced by the adhering canes become spiral, and ornament the surface. If well softened and marvered before the drawing and twisting, the streaks spread till they meet; or if, before being drawn, the mass be redipped into the pot of crystal glass, and then twisted, the spiral lines of color or enamel become internal. By the repetition of this process, spirals can be formed

within spirals; and by placing the filigree canes side by side, and welding them together, very curious and intricate patterns are obtained.

The *Venetian ball* is simply a number of pieces of waste filigree glass collected together without regular design; they are then introduced into a globe of transparent glass, which is made to collapse upon the filigree fragments within by suction; that is to say, by the blower drawing in his breath. The round heavy paperweights, which generally contain regular devices, are formed in the same manner, and the lens-like shape of the crystal enhances the effect by magnifying the incrustated ornament.

The *mille-fiore* or *star-work* of the Venetians is formed by placing lozenges of glass, cut from the ends of colored filigree canes in the interval between two transparent cones, as shown in Fig. 198, and then, after reheating the whole, exhausting or sucking out

Fig. 198.

the air by means of a blowing-iron attached to the neck, A. The piece being then rewarmed becomes one homogeneous mass, which can be shaped into any required form, for *tazzas*, paperweights, *et cetera*. In forming such incrustations, it often happens that, from the unequal contraction between the object and the crystal by which it is surrounded, there is much difficulty in the annealing, and, to avoid the

risk of fracture, the contained object must be made of materials expanding and contracting like the glass or crystal itself.

Glass-mosaic, which is often confounded with *mille-fiore*, is produced by threads or small canes of variously colored opaque or transparent glass, of uniform lengths, ranged vertically side by side, in single threads or masses, so that the ends shall form grounds agreeably to some prefigured design. When submitted to heat sufficient to fuse the whole, the four sides at the same time being pressed together so as to exclude the air from the intervals between the threads, the result will be a thick slab of variegated glass—Fig. 199—exhibiting, for all parallel sections, the same figure or pattern.

Fig. 199.

Hence, when cut into veneers, either in the direction shown by the dotted lines, or obliquely or longitudinally, it will yield a number of slabs or layers of the same uniform design. The thin rods of glass employed for this purpose are composed of very easily fusible glass of all possible colors and shades, and are prepared in manufactories erected expressly for this purpose.

In these manufactories, masses of colored glass are prepared, from which a kind of cake is formed, and this is converted, with the aid of a sharp hammer and an anvil, first into slabs, and then into the thin rods above-mentioned. In this form the material is supplied to the artist, who softens it in the flame of a lamp, draws out each rod into a thick thread, and breaks off a piece of the thickness of the intended picture. These pieces are then arranged one after the other, according to the design, on a slab of copper covered with a layer of cement, which serves to fix the picture. When the whole slab is covered, the surface, which is necessarily uneven and irregular on account of the unequal lengths of the rods or threads, is ground and polished. It is unnecessary to observe, that a large mosaic painting formed in this manner is often a work of years.

Venetian frosted glass is obtained by immersing the gathering of hot metal in cold water, quickly withdrawing it, reheating and expanding it by blowing, before it becomes so hot as to melt and weld together the numerous superficial cracks produced by the momentary immersion in cold water. These cracks only penetrate so far as the metal has been cooled by the water, and remain as depressions until the article is finished, when it presents the appearance represented in Fig. 200.

Fig. 200.

The art of making this glass was kept secret by the Venetians, but was rediscovered by Mr. PELLATT a few years ago.

Mr. PELLATT has also invented a method of ornamenting glass with delicate white argentine incrustations of dry porcelain clay, cemented into the solid glass. For this purpose the hot prepared cameo, which may be a small bas-relief or cast, is placed upon the red-hot manufactured vessel or other article; a small piece of liquid glass is then dropped on it, and becomes welded; and if rubbed while hot, the upper coat of fused glass will be spread as thinly as possible upon and around the cameo, behind which are driven any air-bubbles that may be entrapped; thus completely isolating the device between the two glasses. The polishing of the exterior layer gives the white figure a silvery appearance; but, of course, the incrustation may be colored before being applied to the glass. These incrustations require very careful annealing.

Venetian vitro-di-trino is a sort of lace-work, formed by intersecting lines of white enamel, or transparent lines of white or colored enamel or transparent glass, the centre of each mesh or diamond inclosing an air-bubble. It is formed by blowing a gathering in the mould with suitable canes arranged in the interior fluting, as shown in Fig. 195, page 241. It is then reheated, further blown and twisted, as for spiral filigree, the canes being left projecting from the outside, like ribs. By the usual manipulation, a cup or conical

vessel is formed, marked by oblique lines or spiral projections, as shown in Fig. 201. Another similar piece is then made and turned inside out; the projecting canes on this piece are inside, and the spiral lines reversed. The one piece is then placed under the other, as shown in Fig. 202, and the two are welded

Fig. 201.

Fig. 203.

Fig. 202.

together. The ribs or flutes projecting from the two surfaces in contact inclose, during the welding, a portion of air in each diamond, which air gradually assumes the bubble-shape. The vessel is then finished in the ordinary manner, and the lines exhibit the most beautiful regularity, as shown in Fig. 203.

Aventurine Glass is an easily fusible brown, or, in thin layers, yellow glass, interspersed with numerous fine yellow laminae or spangles with a metallic lustre, which give it a peculiar shining appearance. The method of manufacture was long kept secret by the Venetians. It was commonly supposed that aventurine glass was produced by melting scales of metal or mica with the glass; but this opinion was thought to be overthrown when GAHN observed that, under the microscope, these scales appeared as regular three or six-sided tables, perfectly crystalline in structure. He discovered, in fact, that the spangles consisted of metallic copper, crystallized in the form of flat segments of a regular octahedron. FREMY and CLEMANDOT succeeded, however, in preparing this glass by fusing together, for twelve hours, the following mixture:—

Pounded glass,	300 parts,
Copper scales,	40 "
Iron scales,	80 "

and afterwards cooling slowly. The glass obtained was somewhat deficient in lustre, but, like the true aventurine, it contained copper diffused through it in octahedral crystals.

GLASS-PAINTING.—Painting on glass is performed by means of a vitreous mixture termed the flux, combined with a pigment prepared from some metallic oxide. The flux and oxide are simply that combination of ingredients which is necessary to produce a highly fusible colored glass of the required hue; this mixture is reduced to a state of fine powder, rubbed up in oil of turpentine, boiled oil, or sometimes simply with water, and laid upon the glass to be painted, by means of a brush. The glass thus painted or stained with the intended design is then exposed to a heat

sufficient to vitrify the mixture of color and flux, without melting the glass; in other words, the painting is said to be burnt in; the ingredients of which it is composed are converted into a colored glass or transparent picture, while the pane or other article on which it is laid, is only sufficiently softened to cause the complete adherence of the colored glass to its surface.

It is evident, therefore, that the fusing-point of the pigment must be much lower than that of the glass to be painted. Indeed, it is necessary that the former should vitrify at a temperature at which the latter does not sensibly soften; for any considerable softening or yielding of the glass would distort the design. Hence the manifest inapplicability of crystal or lead-glass for painted articles, on account of its great fusibility. On the other hand, common window-glass, or even plate-glass, may be successfully used, and, best of all, the hard Bohemian glass, which contains potassa for a base.

When the coloring oxides employed are such that they are not injuriously affected by the oxides of lead and of bismuth, the flux is usually composed of the following ingredients:—

	Parts.
Quartz in powder,	100
Oxide of lead,	125
Oxide of bismuth,	50

But if these oxides exert an injurious action on the coloring matter, and tend to change its shade, the subjoined composition is used:—

	Parts.
Quartz in powder,	100
Fused borax,	75
Nitrate of potassa,	12·5
Carbonate of lime, free from iron,	12·5

To either of these mixtures or fluxes the proper coloring matter is added, and the composition so formed is introduced into a crucible, and melted into a colored glass. The latter is then reduced to a fine powder, mixed, as has been stated, with oil of turpentine, and used as a common pigment for painting on the less fusible glass. In this operation, a cartoon, or drawing upon paper, is placed below the glass, and the colors are applied on the corresponding lines. In preparing painted sheets or panes of glass, brown or black outlines are generally traced on the one side of the sheet, whilst the colors are laid on the other side; but in painting vessels or other articles, this is not the practice.

One great difficulty of the glass-painter consists in this, that the colors which he lays on have not the same appearance as they are intended to assume in the finished work. The difficulties of the artist on glass, says Mr. TOMLINSON, are of a much more formidable character than those of the artist on canvas; he must be as good an artist as the latter, but he must also have the faculty of seeing his effects as they will appear after the firing, and not as he lays them on; for the coloring oxides which he employs, especially when mixed up in their fluid vehicles, are dark, dusty, and disagreeable in color, and have nothing in common with the bright and beautiful effects we admire in a stained-glass window. When the same figure or pattern is to be repeated many times, it is, in some cases,

printed on the glass with a gentle pressure from an engraved metallic plate, or wooden block, boiled oil being used as the vehicle for the coloring oxide. The pane, having been prepared either by painting or printing, is exposed in an oven or muffle to a temperature sufficient to fuse the vitreous flux and dissolve the coloring material. The glass selected for the purpose of the stainer should be clear and colorless, in order to bring out the colors well; and difficult of fusion, so that the flux and metallic oxide may form a colored glass upon its surface before it shows any tendency itself to fuse. A glass containing a small proportion of alkali, such as crown-glass, is fit for the purpose.

SPUN GLASS.—There is no one who has not heard statements relative to the discovery of a malleable glass, one memorable instance of which is mentioned in the Historical Notice, page 186. If, by malleable glass, be understood a glass capable of being spread out into thin plates under the action of the hammer at the ordinary temperature, everything leads to the belief that this marvel never was, and will not for a long time be realised. If, on the contrary, it means only the ductility of incandescent glass, there remains in this respect little to be accomplished. It is, in fact, on this property that the whole art of the glass-maker depends. But whilst, in the ordinary operations of glass-making, the ductility of the glass is never pushed to its utmost limits, these limits are almost reached in the curious art of spinning glass into thread.

The art of spinning glass consists in drawing it out into threads when softened, by means of a wheel on which the thread is wound. By this means the art has been attained of spinning glass with astonishing rapidity. The drawn out end of a glass rod has only to be attached to a revolving drum, whilst the rod whence the thread proceeds is held in the glass-blower's lamp, in order to obtain in a few minutes several ells of spun glass. The thread possesses, of course, the color of the glass; but its tenuity is so great that the color is scarcely perceptible, unless very deep shades have been employed.

It has already been stated that when a piece of hollow glass is drawn out, the hole is always preserved, however fine be the thread. M. DEUCHAR took a piece of thermometer tube, the interior diameter of which was very small, and drew it out into threads. The drum which he used was three feet in circumference, and as it made five hundred turns per minute, he obtained thirty-two thousand ells of thread per hour; so that the thread was of extreme fineness, and its interior diameter was scarcely calculable. This thread was, however, hollow; for being cut into pieces of an inch and a half in length, and placed on the receiver of an air-pump, one end inside and the other out, it allowed the mercury to pass through in small shining filaments when a vacuum was made in the receiver.

The thread obtained from a small piece of window-glass, cut with a diamond, presents a very brilliant lustre; seen with the microscope, it exhibits a flattened form, with four very distinct right angles. It is very probable that it owes to this particular form the superiority of its lustre, for the threads obtained from round pieces of glass had always a dull appearance.

When glass of different colors is fused or welded together in one tube, the thread obtained from it preserves all the original colors without any mixture taking place, or any interruption being observable; but most of the colors become tarnished by the operation, particularly the yellow, which disappears; the black even sometimes passes to brown; the purple and green are a little altered, but the blue stands well.

The samples of spun glass are as pliable as silk, and may easily be wound in the manner of common thread, and employed as ornaments. To the touch they feel like hair, and like it may be curled in a permanent manner by rolling them on a hot iron. Threads from black glass have so much resemblance to black hair, that they are often confounded. It is well known that in the last century perukes were manufactured of glass thread, which is sometimes still used to make very brilliant head-dresses. Its glossy appearance, its great durability when not exposed to rough usage, as well as the low price of glass, naturally suggested to manufacturers the advantage of making it a material for spun fabrics. It has even been woven into stuffs, but hitherto this curious manufacture does not appear to have been attended with much success. It has been alleged, indeed, not without reason, that articles of clothing made of glass might be attended with some danger from the filaments becoming detached, and being drawn into the lungs by respiration. KNAPP states, however, that this branch of manufacture has lately been revived with success by OLIVI, DUBUS-BONNEL, and BOUILLON; and that DUBUS, in particular, is said to have succeeded in producing glass thread that can be knotted, and woven on JACQUARD'S loom into fabrics which are equal in every respect to the most beautiful gold and silver brocade. He adds that the particulars of this manufacture have not yet been made public, and the Editor cannot help thinking that its success has been greatly exaggerated.

VII. SOLUBLE GLASS.—Soluble glass is a compound, the knowledge of which would have spared the glass-makers many faults. It is, as has been stated, a simple silicate of potassa or soda, or a double silicate of these two bases. What is remarkable, this body is soluble in boiling water without a residue, though scarcely affected by contact with cold water. Nevertheless, it is very evident that such a glass must be strongly hygrometrical, and, among the numerous examples which might be cited, the Editor limits himself to the following, to show the inconveniences which arise from this. In 1780, Bohemian glasses, the process for which was then a recent importation, were made simultaneously in France by the two following receipts:—

	At Bayel in Champagne.	At Elmbac in les Vosges.
Silica,.....	100	100
Potassa,.....	100	100
Lime,.....	none	100

Now, while the Vosges glass was unalterable by the air, that of Champagne was wanting in clearness, brilliancy, and solidity, and attracted the moisture of the atmosphere to such an extent, that the hollow feet of drinking-glasses became filled in the warehouses with

a saturated solution of carbonate of potassa. To this fact, one might add many others which would prove the indispensable necessity of lime or of oxide of lead, for the making of glasses to be capable of resisting the action of water or of moist air.

Soluble silicated alkali or water-glass may be prepared by various processes. If sand be used, fifteen parts of fine sand, thoroughly incorporated with eight parts of carbonate of soda, or with ten of carbonate of potassa, and one of charcoal, fused in a furnace, will produce a silicated alkali which is soluble in boiling water. Messrs. RANSOME obtained this silicated alkali by dissolving broken flints in a solution of caustic alkali at a temperature of 300°.

This water-glass has been applied to several important purposes, three of which are especially noticed.

To protect Building-stones from decay.—The stone surfaces of buildings, by being exposed to the action of the atmosphere, become liable to disintegration from various causes. Moisture is absorbed into their pores. The tendency of their particles to separate in consequence of expansion and contraction, produced by alternation of temperature, is thus increased. Sulphurous acid is always present in the atmosphere of coal-burning cities, and cannot but corrode the calcareous and magnesian ingredients of oolites and dolomites. It is true that good stone resists these sources of injury for an indefinite time, but such a material is rarely obtained. As a preventive of destruction, whether arising from physical or chemical causes, it has been proposed to saturate the surface of the stones with a solution of water-glass.

It is well known that the affinity of silica for alkali is so feeble, that it may be separated from this base by the weakest acids, even by carbonic acid. According to the expectation of those who recommend the silification of stone, the carbonic acid of the atmosphere will set the silica free from the water-glass, and the silica thus separated will be deposited within the pores and around the particles of the stone. The points of contact of these particles will thus be enlarged, and a sort of glazing of insoluble silica will be formed, sufficient to protect the stone from the effects of moisture, *et cetera*. This cause of protection applies chiefly to sandstones. But wherever carbonate of lime or carbonate of magnesia enters notably into the composition of the building stone, then an additional chemical action, also sheltering the stone, is expected to take place between these carbonates and the water-glass. An insoluble salt of lime may be looked for, whenever a solution of water-glass is made to act on the carbonates of lime or magnesia existing in oolitic or dolomitic building stones.

This expectation, however, has not been altogether realized by experiment. Mr. CHARLES A. SMITH, a gentleman eminently conversant with building materials, immersed a piece of Caen-stone in a solution of silicate of potassa in the month of January, 1849. This fragment, together with a portion of the block from which it had been detached, was placed on the roof of a building in order that it might be fully exposed to the action of atmosphere and climate. After five years the silicated and the unsilicated specimens were found to be both in the same condition, the two being equally

corroded. But whatever ultimate results may ensue from this process, the immediate effects on the stone are remarkable. Two portions of Caen-stone were exhibited, one of which had been soaked in a solution of water-glass two months before. The surface of the unsilicated specimen was soft, readily abraded when brushed with water, and its calcareous ingredients dissolved in a weak solution of sulphurous acid. The silicated surface, on the other hand, was perceptibly hard, and resisted the action of water and of dilute acid when similarly applied.

Another proposed use of the water-glass is that of *hardening cements, mortar, et cetera*, so as to render them impermeable by water.

Fourteen years since, ANTHON of Prague proposed several applications of the water-glass. Amongst others he suggested the rendering mortars waterproof. He also suggests that this substance might be beneficially employed as a substitute for size in whitewashing and staining walls. It was demonstrated by several experiments that carbonate of lime, mixed up with a weak solution of water-glass, and applied as a whitewash to surfaces, was not washed off by sponging with water, and that common whitewash, laid on in the usual manner with size, was rendered equally adhesive when washed over with water-glass.

The Stereochrome of FUCHS.—The formation of an insoluble cement by means of the water-glass, whenever the carbonic acid of the atmosphere acts on this substance, or whenever it is brought in contact with a lime-salt, has been applied by FUCHS to a most important purpose. The stereochrome is essentially the process of fresco-sicco invested with the capability of receiving and perpetuating works of the highest artistic character, and which may be executed on a vast scale. This chemist's method is as follows:—

Clean and washed quartz-sand is mixed with the smallest quantity of lime, which will enable the plasterer to place it on the wall. The surface is then taken off with an iron scraper, in order to remove the layer formed in contact with the atmosphere; the wall being still moist during this operation. The wall is then allowed to dry; after drying it is just in the state in which it could be rubbed off by the finger. The wall has now to be fixed, *id est* moistened with water-glass composed as follows:—

	Centesimally.
Silicic acid,	23·21
Soda,	8·90
Potassa,	2·52
Water,	65·37
	100·00

The specific gravity of the solution is to be 3·81. This operation is usually performed with a brush. The wall must be left in such a condition as to be capable of receiving colors when afterwards painted on. If, as frequently happens, the wall has been too strongly fixed, the surface has to be removed with pumice, and to be fixed again. Repaired in this manner, the wall is suffered to dry. Before the painter begins, he moistens the part on which he purposes to work with distilled water, squirted on by a syringe. He then limns: if he wishes to repaint any part, he moistens again.

As soon as the picture is finished, it is aspersed over with water-glass. After the wall is dry, the syringing is continued as long as a wet sponge can remove any of the tint. An efflorescence of soda sometimes appears on the picture soon after its completion. This may either be removed by syringing with water, or may be left to the action of the atmosphere. Not to dwell on the obvious advantages possessed by the stereochrome over the real fresco—such as its admitting of being retouched and its dispensing with joinings—it appears that damp and atmospheric influences, notoriously destructive of real fresco, do not injure pictures executed by this process.

The following crucial experiment was made on one of the pictures. It was suspended for twelve months in the open air, under the principal chimney of the New Museum at Berlin; during that time it was exposed to sunshine, mist, snow, and rain, and nevertheless retained its full brilliancy of color.

The stereochrome has been adopted on a grand scale by KAULBACH, in adorning the interior of the great national edifice at Berlin, already alluded to. These decorations consist of historical pictures—the dimensions of which are twenty-one feet in height, and twenty-four and three-quarters in width—single colossal figures, friezes, arabesques, *et cetera*. On the effect of the three finished pictures, it has been remarked by one whose opinion is entitled to respect, that they have all the brilliancy and vigor of oil paintings, while there is the absence of that dazzling confusion which new oil paintings are apt to present, unless they are viewed in one direction, which the spectator has to seek for.

MR. A. CHURCH has suggested that, if the surface of oolitic stones—such as Caen-stone—is found to be protected by the process already described, it might be used, as a natural *intonaco*, to receive colored designs, *et cetera*, for exterior embellishings; the painting would then be cemented to the stone by the action of the water-glass.

MR. CHURCH has also executed designs of leaves on a sort of terra-cotta, prepared from a variety of WAX's silica rock, consisting of seventy-five parts clay, and twenty-five of soluble silica. This surface, after being hardened by heat, is very well adapted for receiving colors in the first instance, and retaining them after silication.—*Timbs*.

KUHLMANN remarks that the contact of lime with silicate of potassa, always determines the decomposition of this salt and its transformation into silicate of lime, which retains the coloring matter, and even carbonic acid, as lately supposed by M. FUCHS; but when the colors are applied on bodies which do not react on the soluble silicate—such as wood, iron, glass, *et cetera*—it becomes necessary to seek for conditions of insolubility in the reaction of the coloring matter on this silicate. On wood the difficulty may be removed by the application, before the silicious painting, of a sufficiently thick covering of chalk, which may be applied with zinc, or fixed with a very little silicate.

Even when the decompositions of the alkaline salt are determined by the coloring matter itself, there still remains one serious inconvenience: this is the exudation, during damp weather, of carbonate of potassa to

the complete expulsion of the salt. This chemist for a long time sought for a remedy for this serious injury to silicious paintings; he often conferred on this subject with those members of the Academy best acquainted with vitrification, and having been aided by their advice, KUHLMANN sought in various chemical changes for a remedy, and ascertained that washing the painting with a weak solution of chloride of ammonium, enables one to attain absolute insolubility of the color, but chloride of potassium remains, which spoils its brilliancy until its complete expulsion by repeated affusion with water. As the number is but small of chemical reagents, which have the property of consolidating potassa by forming with it insoluble compounds in the color itself, but without eliminating it, perchloric acid and hydrofluosilic acid are the chemical agents which first offer themselves to the mind.

In a theoretic point of view, there only remained to choose between them; but, in an industrial sense, hydrofluosilic acid was the only one on which his mind fixed itself. He ascertained so frequently that careful washing with hydrofluosilic acid much augmented the stability of these colors, and determined their complete insolubility, that he did not hesitate to point out the utility of this agent in every kind of silicious limning, but especially in painting on glass, provided that it is used in very weak solution; for in the concentrated state it has the remarkable property of dissolving most of the oxides, which property will be very valuable for industrial purposes, when this acid can be sold at a moderate price.

The silicious colors on glass have a certain semi-transparency which it is important to preserve, but which gradually diminishes by the action of water. Glass painted with silicates has been subjected to boiling in water without the colors being detached; these tints have even appeared brighter when seen by reflected light; but if, after this apparent improvement, the effect is examined by transparency, the hues are found to have become duller, which is to be attributed to the opacity which they had acquired, resulting from the solution of a portion of silicious cement, which acts on these colors as oil does on paper. The careful employment of hydrofluosilic acid gives a complete insolubility to paintings on glass; but, like chloride of ammonium, it slightly diminishes the transparency. One might perhaps apply, at long intervals, a slight varnish of pure silicate of potassa to paintings on glass which are exposed to rain. Long experience can alone determine this point. This varnish would advantageously replace the essences now used in the application of certain colors on glass and porcelain; it would not, like the essences, be subject to the drawback of spoiling certain colors by the reduction of the oxides or of the coloring salts.

STATISTICS.—Considering the vast importance of glass, and the peculiar facilities possessed by Great Britain in her ample stores of coal, and the possession of nearly all the materials for the manufacture, it might have been imagined that this country would not only have fully supplied her own wants, but would long ago have furnished a large portion of the world with glass, as with many other exports. It might be sup-

posed, also, that the various necessary, convenient, and ornamental purposes to which glass is applied, would have been held as a sufficient reason for exempting it from taxation, or at least for reducing the duties to the lowest possible limit. But so far was this from being the case, that the most exorbitant duties were imposed, and were exacted in the most oppressive manner; which not only limited the demand for glass, by directly increasing the price, but operated indirectly with most injurious effect, by fettering the operations of the manufacturers, and preventing them from making experiments, and introducing new processes and improvements.

As illustrative of the amount of the duties, which are exhibited more at large in the appended tables, it will be seen that in 1813 they were raised to not less than four pounds eighteen shillings a hundredweight on plate and flint glass, and three pounds thirteen shillings and sixpence on crown. With such enormous duties on one of the modern necessities of life, the result of ignorant legislation, it was impossible for this country to enter into fair competition with other nations, or even to keep pace with a rapidly increasing population. On the contrary, despite the increase in population, and the still greater increase in wealth in the interim, the consumption of flint and plate glass in 1813, and many subsequent years, was less than it had been in 1794, when the duty on these glasses was only one pound two shillings and twopence farthing a hundredweight. Again, it is stated by the late Mr. PORTER, that in 1801, with a population of only sixteen millions, the quantity of glass used was three hundred and twenty-five thousand five hundred and twenty-nine hundredweight; and in 1833, with a population of twenty-five millions, the quantity was no more than three hundred and sixty-three thousand four hundred and sixty-eight hundredweight—an increase of one-eighth, while the population had increased in the proportion of one-half.

By the imposition of the income-tax, the late Sir ROBERT PEEL was enabled to abolish, along with many other injurious indirect taxes, the excise duties on glass, which were repealed from the 5th April, 1845; and MACCULLOCH justly remarks, that the beneficial influence of this liberal and most judicious measure is obvious in the improved quality, the increased cheapness, and greater variety of descriptions of glass in the market. At the meeting of the Society of Arts, in 1856, to which reference has already been made in the course of this article, Mr. W. A. SWINBURNE, of the celebrated glass-making house of that name, alluded to the different price of glass in former times, as compared with the present; speaking of three shillings and sixpence or four shillings a foot as having been paid to glaziers now living for glazing ordinary-sized crown glass in sashes, for which now, perhaps, only as many pence could be obtained. In the case of plate-glass, he held in his hand a tariff used by their house, dated 1771, two years before the establishment of the British Plate-Glass Company, wherein the price of a chimney mirror fifty inches long by forty inches wide, a very usual size, and now in common demand, was quoted at sixty-one pounds three shillings! The price of this plate before

the repeal of the duty in 1845, was nine pounds nine shillings to ten pounds; after the repeal of the duty, about eight pounds; in 1854, four pounds ten shillings; and in 1855-6, about four pounds four shillings. So much had the public benefited by the reduction of the price of glass.

But, as may be supposed, this reduction in price, as well as the great improvement in quality, did not solely arise from the mere repeal of the duties. It arose also, in great measure, from the removal of those intolerable fetters which were previously imposed on the manufacturer by the excise regulations. During the excise reign, says Mr. PELLATT, in his *Curiosities of Glass-making*, no pot could be moved from the spot where it was dried, to be placed in the annealing arch, without a notice in writing to the supervisor; a second notice was required for gauging; a third for setting it in the furnace; again, for filling the pot; and another for lading it out; whilst the maker was forced to comply strictly with the act of parliament, by giving the officer six hours' notice for each of these intricate and vexatious requirements.

Again, with reference to the subject of annealing, the same able writer remarks:—When the excise upon glass existed, the lear was secured by fastenings and locks—supplied by the Government officer at the expense of the trader, and safely secured every Friday or Saturday, and not re-opened till the Monday following. During the whole of the week, the officer had the surveillance of the lear, but especially of the sorting-room, at the delivery end of the lear, which was only entered at the stipulated act of parliament periods. If a link forming part of the endless chain running under the lear, connected with the machinery drawing down the pans, accidentally broke in the night, and the officer should happen to be absent—which was rather the rule than the exception—either the whole works must be stopped, or some mode adopted for the learner to repair the mischief not strictly in keeping with the act; so that while the principal was quietly reposing in his bed in imaginary security, his servant, unknown to him, had almost necessarily incurred ruinous excise penalties. The excise officer gauged the liquid glass in the pots, which he had the option of charging by weight, at a specific gravity of 32·00; and should the manufactured annealed goods ultimately not amount to two-fifths of that estimate, he had to pay the difference. The lear charge was always considered to be the chief security, as indeed it really was; still, with the utmost excise vigilance, the trader occasionally defrauded; but owing to the great heat of the arch, and the usual excise securities, the revenue was, on the whole, well secured at the lears. Had the lears or kiln been the only departments of the works under excise survey, the manufacturer would not have been so much inconvenienced. The surveillance of the pots was his chief annoyance, since it required endless trouble, and subjected the manufacturer to danger of exchequer prosecutions. To throw into the pots ever so small a piece of metal, during the working, incurred a penalty of fifty pounds for every offence. Neither plate-glass nor bottle-glass manufacturers were subject to the surveillance of the pots: this made it exclusively injurious to the flint-glass maker, and was

almost a prohibition of alteration of tint, or experiments, and consequent improvements. It is matter of astonishment how flint-glass works existed at all, under such a concentration of commercial and manufacturing hindrances as were imposed by the excise regulations; happily, the incubus exists only in reminiscence.

While the greatest stimulus was given to the crown and sheet glass manufacture by the abolition of the duty in 1845, that abolition has produced a somewhat paradoxical result, which is thus stated by Mr. HENRY CHANCE:—While the quantity of glass made has increased in the proportion of three to one, the number of manufacturing firms has diminished in the proportion of one to two. In 1844 there were fourteen companies engaged in the manufacture. In 1846 and 1847, following the repeal of the duty, the number had increased to twenty-four. The glass trade, after the removal of the heavy burden imposed upon it, seemed to offer a fair opening for money seeking investment. The demand for glass was so great that the manufacturers were in despair. Glass-houses sprung up like mushrooms. Joint-stock companies were established to satisfy the universal craving for window panes. And what was the result? Of the four-and-twenty companies existing in the year 1847, there were left, in 1854, but ten. At this time there are but seven in the whole United Kingdom. Two, established in Ireland, have ceased to exist. In Scotland, the Dumbarton works, once famous, were closed in 1831, by the death of the partners, afterwards re-opened, and again closed. The seven now existing are all English.

While thus diminished in number, the immense extent and resources of the principal great glass-houses now existing may be inferred from the fact already alluded to, namely, that the firm of CHANCE and Company executed the large order in sheet-glass for the Great Exhibition structure of 1851 without materially affecting their power of executing their general orders. In such immense establishments, experiments, now untrammelled by the meddling officiousness of an absurd legislation, can be executed on a large scale, and vast improvements have been effected. Minute, and apparently unimportant changes, perceptible only to those near at hand, have in silence done their work.

Still, as one of the eminent members of the firm above referred to remarks, the development both of the processes and applications of the glass manufacture is incomplete. Sir JOSEPH PAXTON's glass arcade, stretching over the streets of London, and Dr. SLEIGH's city of glass, in which invalids will inhale the gentle air of Madeira,—these are faint foreshadowings of the destiny of this wonderful substance. And, perhaps, the day may come when some future chronicler of glass shall smile at the barbarians of the nineteenth century, who could not make window-glass without defects, and shall exhibit those defects as the curiosities of a by-gone age.

The annexed table, from MACCULLOCH, shows the state of the manufacture, quantity exported, and amount of duties, a few years previous to their repeal :—

I. Account exhibiting the Quantities of the different descriptions of Glass manufactured during each of the Three Years ending with 1842, with the Quantities exported, the Rates and Produce of the Duties, *et cetera*.

Description of Glass.	Quantity manufactured.	Quantity exported.	Rate of Duty.	Gross Amount of Duty.	Drawback on Glass exported.	Nett Amount of Duty (Excise), after deducting drawback and other legal allow- ances
	Cwts.	Cwts.		£	£	£
Flint-Glass. 1840	104,889	19,913	{ To 15th May, 1840, 18s. 8d. } per cwt.; since, 18s. 8d. per cwt. and 5 per cent.	101,029	21,199	79,830

All kinds of glass may now be imported free of duty, except flint cut glass, flint colored glass, and fancy ornamental glass of every description, on which there remains a customs' duty of ten shillings the hundred-

weight. The residuary customs' duty of one shilling and sixpence a hundredweight on shades and cylinders, and any kind of window-glass, white, or stained of one color only, expired on the 5th April, 1857.

II. A return of the Rates of Duty on Glass in 1813, with the Quantities of each Kind of Glass retained for Home Use, and the aggregate Nett Revenue in each Year, from 1813 to 1842, both included, noting the Periods when any Alteration of the Duty took place, and the Amount of such Alterations.

The following tabular statement, exhibiting the amount of the imports of the different kinds of glass enumerated, for the three years ending 31st December,

1855, and the exports of glass, of *foreign and colonial manufacture*, during the same period, is extracted from the Trade and Navigation Returns:—

	IMPORTS.			EXPORTS.		
	1853.	1854.	1855.	1853.	1854.	1855.
Window-Glass, and Shades and Cylinders,....	Cwts. 27,577	31,639	25,420	5,485	3,012	1,126
Plate-Glass,	Lbs. 221,304	794,194	749,151	16,415	14,175	21,747
White Flint-glass Goods—except bottles—not cut, engraved, or otherwise ornamented,....	Lbs. 106,621	358,472	378,065	15,980	4,584	3,039
All Flint Cut Glass, Flint Colored Glass, and Fancy Ornamented Glass,	Cwts. 6,893	10,692	9,402	1,143	846	585

The above exports refer to glass of foreign and colonial manufacture. The great falling off in these exports during the years 1854 and 1855, is obviously attribut-

able to the war with Russia; but this effect scarcely appears in the following statement of the exports and declared value of glass of *British manufacture*:—

	Hundredweights exported.			Declared value.		
	1853.	1854.	1855.	1853.	1854.	1855.
Flint-Glass,	47,548	53,072	39,283	£162,849	180,896	141,831
Window-Glass,	39,158	34,522	21,473	58,503	57,761	33,821
Bottles,	457,787	481,262	513,128	248,458	274,832	279,620
Plate-Glass—value only,				48,730	35,755	52,283
				£518,540	£549,244	£507,555

It is worthy of remark, that in the year 1844, the year before the excise duties were repealed, and with all the advantage of a drawback, the total exports of glass, of British manufacture, were only of the declared value of twenty-six thousand six hundred and ninety-four pounds; whereas, it will be seen from the preceding table, that in 1855, or ten years after the repeal of the duties, they amounted in value to upwards of half a million sterling.

GLYCERIN.—The basic principle of the several substances contained in the fats of animals, as also of several compounds of vegetal origin, has been called *glycerin*. SCHEELÉ, its first discoverer, named it *the sweet principle of fat*; but since then, the several investigators who have worked upon the subject have modified this title to that above given, from the Greek word, signifying *sweet*. As already noticed—see vol. i., page 406—this body has not as yet been fully investigated, and considerable diversity of opinion exists regarding its origin and nature. It is generally acknowledged to be an oxide of a compound radical, which, upon the decomposition of the stearin, margarin, or olein of the fats, assimilates water, and acquires the composition which analysis has assigned to glycerin. Respecting the nature of this radical, much speculative reasoning has been indulged in. BERZELIUS designated it *lypyl*, and contended that the definite bodies in the natural fats were salts of the fatty acids, with the oxide of this radical. LÖWIG, on the contrary, with whom many concur, terms it *glycil*; all, however, seem to have attributed to it the composition $C_3 H_2$, and agree that, by the assimilation of oxygen and the elements of water, it becomes $C_6 H_8 O_6 = 2 (C_3 H_2) + O_2 + 4 HO$.

PREPARATION AND PROPERTIES.—Originally, glycerin was prepared by a rather troublesome process, and necessarily in small quantity. Olive oil, or any of the natural fats, was boiled with litharge—oxide of lead—and water, till saponification was effected; the fluid matter remaining was decanted, and submitted to the action of sulphide of hydrogen— HS —by which the portion of the metallic base held in solution was precipitated in the form of sulphide. After filtration, the liquid was exposed to careful evaporation under 212° , till all the water was removed, and a viscous fluid remained. This was the glycerin. Prepared so, it is a faintly yellowish fluid, with an agreeable sweet taste; it is soluble in water, which it attracts from the air, and likewise in alcohol, but not in ether. The alkalies, and several metallic oxides and salts, more especially those which are known to deliquesce in the air, are dissolved by it to such an extent that it ranks next to water in solvent power. With acids it invariably yields acid salts. It is a very stable compound, being persistent in air; it suffers partial decomposition when slowly distilled, and passes over unchanged when a temperature of from 500° to

600° is applied; but, when subjected to a heat beyond this, it is entirely transformed into another definite body, known as *acrolein*, acetic acid, and inflammable gases. Thrown upon live coals, or heated in contact with air, it burns with a blue flame; heated with phosphorus in a closed tube, it yields acrolein.

When largely diluted with water and mixed with yeast, after long standing at a temperature between 68° and 85° , it yields, according to REDTENBACHER, a small quantity of gas and metacetic or propionic acid— $C_6 H_8 O_3 = C_6 H_8 O_6$, minus three equivalents of water.

DOBEREINER found that, by the action of spongy platinum, it was converted into an acid. Concentrated nitric acid transforms it into water, carbonic, and oxalic acids; and, by operating upon it with hydrochloric acid and binoxide of manganese, formic acid is produced by cautiously treating it with dilute sulphuric acid. VOGEL states that it may be converted into glucose, which requires confirmation, for the tendency is for both to unite and form an acid salt. PELOUZE found this to be the case; for on mixing one part of concentrated sulphuric acid with half a part of glycerin, much heat was developed, and glycero-sulphuric acid resulted, the formula of which was ascertained to be $C_6 H_7 O_6 SO_3$, $HO SO_3$.

Glycerin is heavier than water, being at 59° of the density 1.28; its composition, deduced from the analyses of itself and its salts by PELOUZE, is:—

		Centesimally.
6 Eqs. of Carbon,.....	36	39.130
7 Eqs. of Hydrogen,.....	7	7.609
5 Eqs. of Oxygen,.....	40	43.478
1 Eq. of Water,.....	9	9.783

$$\text{Formula:—} C_6 H_7 O_6, HO = C_6 H_8 O_6.$$

Until the late investigations of BERTHOLLET it was believed that glycerin was incapable of forming neutral compounds with acids; but from these researches it is evident that such a supposition can no longer be entertained, since synthetically the above-named eminent chemist produced compounds in every respect identical with the natural fats both of animal and vegetal origin, by the union of the respective acids of such bodies with glycerin. He found that this base is capable of uniting with one, two, or three equivalents of the acids respectively, the triacid body being similar in all its properties to the natural fat of which such acid may be a component. The several compounds are prepared by heating the acid and glycerin together, during three or four days, in close vessels, at 212° ; or for as many hours, at a temperature varying from 360° to about 500° , employing an excess of one or other of the constituents, according as the mono-di- or tri-acid compound is to be produced. By treating the mixture of

fatty acid and glycerin with hydrochloric, sulphuric, phosphoric, or tartaric acid, in a close vessel, for some hours, at the boiling point of water, the same results are obtained. These several formations are attended with the separation of the elements of water, which, however, does not take place in proportion to the equivalent

of acid which combines with the glycerin, though the analogous compounds of each of the fatty acids correspond in this respect. This disposition of the bodies will be better understood by collating the symbols of the several fats and their constituents, as in the following :—

				Stearic acid.		Glycerin.

Until within the last few years, glycerin was invested only with scientific interest, and its production was of rare occurrence; now, however, it has acquired considerable repute, and is manufactured in large quantities. In medicine it is calculated to render very great services as a vehicle for exhibiting the various remedies, besides being itself a specific for many ailments. Under certain circumstances, it acts as a valuable antiseptic, and a solvent in the cure of many kinds of urinary calculi. In perfumery and cosmetics its use is daily extending, being, on account of its emollient qualities and freedom from greasiness, an admirable ingredient for soaps, pomade, hair tonic, *et cetera*. Photographers likewise have latterly employed it with success. In these and several other appliances it is likely that in a short time its consumption will be much greater than at present, although it has already been manufactured extensively.

Several modified processes are pursued to obtain it, some of which may be briefly noticed. As already stated, it was procured as a secondary product in the manufacture of lead plaster. Equal parts of powdered litharge and olive oil were mixed with water, and the mixture boiled till a plumbiferous soap resulted from the combination of the oleic and other fatty acids and metallic oxide. During the ebullition, the contents of the vessel were kept stirred, and water supplied from time to time, to make up the loss by evaporation. When the yellow color of the litharge disappeared, and the mass looked white and homogeneous, the fire was removed, and the liquid portion decanted, and afterwards treated with sulphide of hydrogen, as long as any precipitation occurred. A succeeding filtration removed the metallic sulphide, and after this the liquid was evaporated at a water-bath heat, and finally in an exhausted receiver over sulphuric acid. When the evaporation is performed in contact with the air, the fluid acquires a brownish tinge. JAHN'S process is similar to the foregoing, only that the proportion of the substances is varied. Instead of equal quantities, he takes five parts of litharge and nine of olive oil, and proceeds with them as described, and boils the soap with water three successive times, decanting and mixing the three solutions together. The tinge is removed by filtration through animal charcoal, or by digesting the weak

liquor with a mixture of animal and freshly-prepared wood or peat charcoal, filtering and concentrating in the usual way. By this course, he obtained about seven ounces of glycerin from the above quantity of materials. Glycerin can be obtained from the mother liquor of the soap factories, by adding to it a slight excess of sulphuric acid, heating the solution with carbonate of baryta, filtering, and, after the filtrate has been concentrated by evaporation, extracting the glycerin with alcohol. On distilling off the spirit, the glycerin remains. It may likewise be readily prepared by dissolving castor oil in absolute alcohol, and passing hydrochloric acid gas through the fluid. The fatty ethers are washed away by water, and the residuary fluid affords the glycerin in a state of purity on evaporation. Any adhering fatty matter is separated by digesting the liquid in ether, and decanting the latter.

CAR'S process for the preparation of glycerin from the mother waters of the saponification of stearin with lime in the manufacture of stearic acid candles, is as follows :—The liquid drawn off from the lime-soap is reduced by evaporation in steam kettles over a naked fire; and, after ascertaining how much lime is present, by precipitating a certain bulk with oxalate of ammonia, collecting the precipitate, drying, burning, and weighing it, with the requisite precautions, the necessary quantity of sulphuric acid to combine with the lime is added, when sulphate of lime falls.

After its subsidence, the clear liquid is decanted into another receptacle, in which it is boiled out of contact with the air, and stirred at the same time by some mechanical arrangement. This ebullition expels all the volatile fatty impurities which may be present, and, consequently, the liquid loses both color and odor. As soon as the solution arrives at a density of 14° Twaddell, it is allowed to cool, when the precipitation of a further portion of sulphate of lime occurs. Should an excess of acid be present, as may be known by its action on tincture of litmus, some chalk or powdered limestone must be added fractionally till the liquid is neutral. After this the boiling is continued as before out of contact with air, during which time the contents of the vessel must be actively stirred, till the solution marks 37·5° Twaddell. The sulphate and carbonate of lime are now collected on a filter, and the filtrate reduced by evaporation, till, upon cooling, it marks 49°, care

being taken to keep it well agitated during the time. If any further quantity of sulphate of lime falls, a repetition of the filtration is necessary. To remove the tinge, the fluid is passed through washed animal charcoal or bone black, when a pure colorless solution of glycerin is obtained, marking 45° ; and, by carefully concentrating it further, a fourth of its weight of water may be removed, when the residuary sirupy fluid indicates 51.2° Twaddell. According to WILSON, the product thus obtained, though superior to that manufactured by the old process, is not absolutely pure, no matter how much care is taken in conducting the operations.

A much more economical method is that introduced by TILGHMANN in 1854. By this process the fatty bodies are broken up into acid and basic substances, through the agency of heat, pressure, and steam, as described at page 433, vol. i., and form separate layers in the recipient, into which the products flow from the condenser. The glycerin, which is the heavier of the two, forms the lower stratum, and the fatty acids the upper; the latter can be readily separated mechanically, and the former left devoid of any other impurity excepting water. By careful concentration, the aqueous matter may be expelled, and the product obtained of a specific gravity of 1.24, and containing only four per cent. of moisture; but, by prolonging the operation, two per cent. more of water may be removed, and the pure glycerin is left of a density = 1.260. WILSON, by injecting superheated steam into a hot solution of fat, succeeded in effecting the decomposition of the latter, and at the same time the fatty acid and glycerin are carried over into the receiver, where they form two layers, as in the preceding instance, and capable of being readily separated.

ANALYSIS.—The analysis of glycerin demands all the expertness of the practical chemist. It may be accomplished by submitting it, or some one of its more definite and permanent salts, to combustion with oxide of copper or chromate of lead. If a salt of this base with baryta or lime be the subject, it may be mixed with the powdered oxidizing agent, introduced into the combustion tube, and burned in the usual way; but when glycerin *per se* is to be analysed, it must be inserted into small glass bulbs, the apertures of which are drawn out to a fine point, and two or three of the latter introduced into the combustion tube, placing three or four inches of the oxidizing agent between them. From five to ten grains will be sufficient for the analysis. Attention should be paid to inserting the bulbs, so that the aperture of each may open towards the sealed end of the tube, in order that the fluid may have to traverse through a longer portion, and come in contact with more of the oxidizing agent than if the bulb part was dropped in first. By this means, a more thorough oxidation of the elements is insured. The water and carbonic acid produced during the burning are severally arrested by chloride of calcium and hydrate of potassa in the usual way, and their quantity determined. When operating upon liquid substances generally, the combustion tube should be longer than when required for solid bodies, to present a greater oxidizing surface to the vapor as it passes off.

Glycerin cannot be readily detected in animal fluids, unless it be present in such quantity as will permit its being extracted and subjected to an elementary analysis; but as it is exceedingly difficult, or nearly impossible, to isolate it pure when associated with other animal matters, this method can rarely be successful. A characteristic test remains, however, whereby the presence of glycerin may be ascertained, in the peculiar bodies to which it resolves itself on being decomposed by heat. The most remarkable of these is acrolein—a substance possessing such an intense and marked odor as to render it unmistakeable. When, therefore, the substance suspected as glycerin, after being deprived as far as possible of all impurities, is rapidly heated either *per se* or with a little anhydrous phosphoric acid, an acrid pungent odor, somewhat analogous to that of the wick of an extinguished candle, is evolved, and this is sufficient proof of the presence of glycerin.

GOLD.—*Or*, French; *Gold*, German; *Aurum*, Latin.—This most precious of the metals, so highly esteemed on account of its rarity, beauty, high specific gravity, non-liability to tarnish or oxidize, and consequent admirable adaptation, both as a medium of exchange, and for articles of ornament, has been known and prized from the most remote antiquity. In its pure state, it is of a rich yellow color, high metallic lustre, but nearly as soft as lead, so that it cannot be used in a state of absolute purity either for jewellery or coinage. It is the most malleable of metals, and with the single exception of platinum, it is the heaviest body in nature, being nearly twenty times the weight of its bulk in water. Gold is almost always found in the metallic state, and in this form is largely diffused over the earth; but in many localities it occurs in such minute and widely-scattered fragments, that it will not pay for working expenses. It is found in many forms—in masses, lumps, fragments or nuggets, dendritical threads, scales, dust, and infinitesimally mixed with the auriferous quartz; but almost always mechanically mixed, and not chemically, as with other metallic ores. Hence, the operations for extracting it from its deposits differ from those required by almost every other metal, in being for the most part purely mechanical. They chiefly consist in pulverization and washing—the high specific gravity of the metal greatly facilitating the latter process. But thoroughly to extract the gold, amalgamation is often resorted to—a quantity of mercury being mixed with the ore, which forms an amalgam with the gold, and is afterwards expelled by distillation. If copper and silver be present, which is generally the case, the former is removed by cupellation, and the latter by a process termed *parting*. These operations will be fully described under their proper heads. They have merely been referred to at present to explain the incidental allusions to the metallurgical department of the subject, which cannot be entirely avoided in detailing the history of the metal, and of modern gold discoveries.

HISTORICAL NOTICE.—From the circumstance that gold occurs in the metallic state, often mixed with the superficial soil and sands of rivers, it was probably the first of the metals known to man. Accordingly, one learns from the sacred record, that gold existed in that

part of the earth's surface which was first prepared as the dwelling of the human race. MOSES states, that the land of Havilah, encompassed by one of the four rivers which watered the garden of Eden, not only possessed gold, but gold of a superior quality; and JOB, who is supposed to have written about 1800 years before the Christian era, alludes to the earth having *dust of gold*. With reference to the remark of MOSES, that the gold of the land of Havilah was good, Mr. NAPIER of Glasgow, in a recent publication on the Ancient Workers and Artificers of Metals, justly regards it as warranting two inferences; first, that gold had been found in other localities than the one referred to; and, second, that different qualities of gold were known in the time of MOSES. But as this, like the other metals, is an elementary substance, and not a compound, it follows that all gold, when pure, must be of the same quality. Hence the further inference, that the workers in metal in the time of MOSES, with all the acknowledged skill of the ancients in metallurgy, were not acquainted with the method of reducing gold to a state of absolute purity. That they were acquainted with the refining of the precious metals to a certain extent, plainly appears from different passages in the Old Testament, in which familiar allusion is made to this operation; and made, too, in terms which seem to imply that the methods then adopted were in many respects similar to those now employed. Silver and gold are purified or separated from foreign ingredients by much the same processes; a knowledge of the one implies a knowledge of the other; and JOB says, surely there is a mine for silver, and a place for gold, which men refine; while DAVID compares the words of the LORD to silver tried in a *furnace of earth*, purified many times. MALACHI is still more particular when, in comparing the Judge of all the earth to a refiner's fire, he says: *he shall sit as a refiner and purifier of silver, and he shall purify the sons of Levi, and cleanse them as gold and silver*. Here there is an evident allusion to the last operation required in the refining of silver—that of cupellation—during which the refiner must place himself at the furnace, and watch till the metal emits a bright flash, which indicates that the process is finished. Gold, as will be afterwards explained, is submitted to the same operation; but it requires a further treatment to free it from the silver with which it is invariably mixed to a greater or less extent; and this operation, known as *parting*, is the only process, essential to the perfect purification of gold, which does not seem to have been known to the ancients. There is, at least, no evidence that they were acquainted with this process; but rather the contrary, from the words of MOSES, which indicate that gold from a variety of sources was then believed to possess essentially different qualities; although, it is true, that the sacred historian may refer to the different states of purity in which the metal was found.

The small per centage of silver which is frequently found in gold in the native state, detracts but little from its beauty or value; and as the ancients appear to have been well acquainted with the methods of separating it from other ingredients, there is little doubt that a large proportion of their gold approached to a state of purity. On the other hand, it is frequently

found combined, or mechanically mixed, with a very considerable amount of silver; and hence it may be presumed, that much of the gold in circulation among the ancients, was merely an alloy of these two metals in those proportions in which they are found in nature. This view of the subject is not only rendered probable by the frequent allusions to *fine gold*, and to gold of different qualities obtained from certain specified sources, such as the gold of Ophir, gold of Parvaim, gold from the north, *et cetera*; but it is confirmed by the fact, that the ancients had a special name for the alloy produced by the mixture. This alloy they termed *electrum*, which PLINY states to have been made artificially by mixing four parts of gold and one of silver. Now, it is worthy of notice, that this is about the mean proportion in which the admixture is found native in many auriferous localities; and hence it may be presumed, that the alloy termed *electrum*, for which the moderns have no distinguishing name, was formed by the ancients artificially to imitate a large proportion of the gold which was then in circulation, separated from all its native impurities, except the silver. BECKMANN, who states positively that the ancients were not acquainted with the art of separating gold and silver, affirms that they used the *electrum* as a peculiar metal; and NAPIER is at the pains to argue, that since they made it artificially, it could not have been considered by them a distinct metal. But BECKMANN evidently means that they regarded the mixture in the same light as brass, bronze, German silver, and other useful alloys are viewed in the present day.

On the whole, there is strong ground for believing that the ancients were unacquainted with the method of *parting* these noble metals—the difficulty arising from the fact, that both of them refuse to be oxidized in the furnace; and yet, there is a shade of doubt on the subject, which renders it peculiarly interesting to the archæologist. Nitric acid is said to have been unknown until it was discovered by the alchemists in the thirteenth century; and yet, Mr. HERAPATH, of Bristol, has lately discovered that the markings on a piece of mummy cloth were made with a solution of silver, which he concludes to have been the nitrate, or common marking ink. Indeed, there is some ground for believing that the ancient Egyptians were acquainted with both nitric and sulphuric acids, with either of which the operation of *parting* is performed; and in that case, they could not be ignorant of the fact that nitric acid dissolves silver, and that it is without effect upon gold. On the other hand, it is difficult to suppose, that if these things were known to the Egyptians, they should not have been known to other nations, and more especially to the Hebrews.

But whatever doubt may rest on this point, it is certain that the ancients, in later times at least, were acquainted with the method of extracting gold and silver from the ores or earths by *amalgamation*, for this process is mentioned both by VITRUVIUS and PLINY, writers who lived about the beginning of the Christian era; and, indeed, it is described by PLINY in terms which show that it was practised nearly in the same manner as at the present day. The mercury employed in this operation, merely combines with the

metals in the earths with which it is mixed, and these must afterwards be separated by other processes.

Both gold and silver, more or less pure, were used by the ancients for articles of ornament and utility, as well as for money. Many of the vessels, and much of the sacred furniture of SOLOMON'S magnificent temple, were made of gold. It is stated also, that in forming the tabernacle in the wilderness, gold was beat into thin plates, and cut into wires or threads to work it in the fine linen, from which it appears that the Israelites had learned from their masters, the Egyptians, the art of gold-beating—an art in which, WILKINS states, in his *Ancient Egypt*, the latter were well skilled.

Gold was also in great demand among the heathens, for the statues of their gods or idols; and some of these are mentioned by HERODOTUS and other historians as of immense magnitude. In connection with this subject, the golden calf which was made by AARON in the wilderness, has furnished a curious subject of controversy to modern commentators. With reference to this object of idolatrous worship, it is recorded that MOSES took the calf, and burned it with fire, and ground it to powder, and strewed it upon the water, and made the children of Israel drink of it. In another passage it is stated, that he stamped it, and ground it very small, even until it was as small as dust. Now, the difficulty connected with this passage, which has so much perplexed well-meaning commentators, is the fact, that gold, however strongly heated, is incapable of being reduced to powder by mere stamping or grinding. It is, as already stated, the most malleable of the metals, and is only *flattened* by stamping. Hence it has been affirmed by Dr. KITTO, on the authority of GOGUET, and reiterated by other commentators as a great discovery, that MOSES was acquainted with the wonderful powers of *natron* as a solvent of gold, and that the golden calf was either burned with *natron*, or was heated in the fire to accelerate the action of that solvent. Unfortunately, however, it so happens that *natron* or carbonate of soda has no such action upon gold as that which is ignorantly attributed to it by these writers; moreover, there is no mention of any solvent being used, or of any intention on the part of MOSES to communicate to the water with which the gold was mixed a nauseous taste, though this appears to be the principal object of the commentators. In fact, as NAPIER justly remarks, the whole chemical or metallurgical difficulty, if any such exists, may be got over, by merely assuming that MOSES fused the gold in the fire to cast it into ingots, which were afterwards beat out into thin plates or leaves, and then would readily admit of being reduced to powder—a process which is practised at the present day to procure an impalpable gold dust employed for various purposes.

Although it can scarcely be supposed that the total amount of gold in circulation in ancient times was so great as at present, yet, from the practice of hoarding the precious metals which then prevailed, and from the limited commercial intercourse which then existed, it seems to have accumulated in some countries, and in particular circumstances, to an incredible extent. Conquerors were accustomed to carry off all the gold they could collect or extort from the subdued nations;

and thus, after a series of successes, the coffers of the victorious monarch and his subjects became replenished with treasure. Hence the vast amount of the precious metals which poured into Rome from the provinces, when she ruled the world. Hence also the enormous accumulation of gold and silver which King DAVID is recorded to have collected during his lifetime for building the temple—an amount which has been estimated at not less than nine hundred million pounds sterling, being more than all that has been raised in all the mines in the known world during the last fifty years. It is scarcely possible to avoid the suspicion that some error has crept into the calculations by which this astounding result is arrived at; but still it is quite certain that immense quantities both of gold and silver were often accumulated in ancient times; and to this day no inconsiderable mystery hangs over the sources from which these treasures were derived. Any little knowledge that is possessed on this subject will be mentioned in enumerating the auriferous or gold-producing localities known at the present day.

It is probable that with the decline of the Roman Empire, the art of extracting and refining the precious metals, like other arts, became to a great extent lost in the darkness of mediæval barbarism. It was then, however, that a new art began to appear, which aimed at a still higher object, and which, however chimerical in its pursuits, struck out many important incidental discoveries, and contributed largely to prepare the way for the triumphs of modern chemistry. Any account of the history of gold would be incomplete which did not make some allusion to Alchemy—the chemistry of the middle ages—by which was elaborated, not gold indeed, but much of the apparatus and many of the principles of a science which is infinitely more important to the human race than gold itself. The object of alchemy was not the refining of the precious metals, but their multiplication, by the transmutation of the baser metals into gold and silver. This pursuit, which may be termed sordid, when viewed in the light of the motives by which it was animated, continued through long centuries of darkness to lead the philosophical world on an *ignis fatuus* chase, terminating in disappointment and misery. HERMES TRISMEGISTUS, who is said to have lived in the year of the world 2076, has generally been quoted as the oldest of the alchemists; but there can be little doubt that the writings attributed to him are entirely spurious. The next great name in the history of alchemy was GEBER the Arabian, who is supposed to have lived not later than the seventh century of the Christian era. A work on alchemy, in three books, bearing the name of this philosopher, was published at Strasburg in 1520, and shows a considerable knowledge of the chemical properties of gold. This metal was termed by the alchemists *Sol*, the sun—and silver, *Luna*, the moon. Medical preparations of gold were termed *solar*, and those of silver, *lunar* medicines. One of the chapters of the work attributed to GEBER is devoted to *The Alchemie of Sol*; and after descanting upon different means of refining and dissolving gold, the author describes several solar medicines, which are all solutions of gold in nitro-hydrochloric acid, with the addition of quicksilver or

mercury, common salt or chloride of sodium, and some other saline matters. If the work be genuine, therefore—a point, however, on which considerable doubt rests—nitro-hydrochloric acid was known as *the* solvent of gold in the seventh century. It was certainly known as such not later than the fifteenth, and was termed by the alchemists *aqua regia*, or the royal solvent, from the circumstance that gold was regarded by them as the king of metals. They esteemed it, indeed, the only pure metal, and believed that all the others were merely adulterations or diseased forms of the same substance, which might be purified or revived by proper processes. Mercury and *aqua regia* were the principal agents which they employed. Not a few of them pretended to have discovered the secret; and some were even so disinterested as to publish the process, but in language understood only by the adepts, and which, it may be safely presumed, was rarely intelligible to themselves. In all cases, the student was directed to prepare his mind by suitable acts of piety and charity; and much religious and cabalistic jargon was mixed with their pretended recipes. From the fact that, in the present state of chemical science, the other metals, as well as gold, are believed to be elementary substances, the Editor deems it unnecessary to say that the doctrine of transmutation was founded on ignorance; but at a time when the elementary nature of the metals was unknown, the belief in their possible transmutation was natural; hence it was cherished by not a few persons of acknowledged eminence. The celebrated ROGER BACON, who flourished in the thirteenth century, was a believer in alchemy, and published a work on the subject. VAN HELMONT acknowledges his belief in the making of gold and silver, though he does not degrade himself, like too many of his contemporaries, by professing to have discovered the secret. BERGMAN, in summing up the evidence for and against the possibility and probability of transmutation, arrives at the conclusion that, unless all historical evidence be rejected, some of the accounts given are entitled to confidence. Even the great Lord BACON has been arraigned as a believer in alchemy, though he rather urges the possibility than the probability of transmutation—a view of the subject so far from meriting ridicule that, in the state of chemical science in his day, it would have been unphilosophical to hold a different opinion. That BOYLE was a sceptic on the subject is well known; but it is less generally known, and in fact it has only lately come to light, that in the ranks of the alchemists must now be enrolled the illustrious name of Sir ISAAC NEWTON. This startling fact is a recent discovery, published for the first time in the last edition of Sir DAVID BREWSTER'S life of that philosopher. It is now known that he was absorbed in this pursuit for years; and that the intense eagerness with which he prosecuted this object accounts, to a great extent, for the apparent indifference which he showed in so long delaying to publish some of his greatest discoveries. Associated with such an array of great names, and more especially with the last, the alchemists are not to be contemned or derided as mere dreamers and visionaries; the pursuit of the object which they had in view was as

natural as their belief in the possibility of its attainment was warranted by the knowledge of the composition of matter then existing; but that which excites a just indignation, which constitutes a fair subject for ridicule, and stamps with infamy many of the professors of the art, is the mixture of fraud, pretension, and hypocrisy, which appears in their writings. It is these unworthy professors that have brought contempt on a pursuit that was prosecuted by many good and great men; and which, however fruitless as regards the immediate object in view, elicited many important facts of which science at the present day reaps the full benefit. The history of alchemy—so replete with empiricism and pretension—teaches also the gratifying fact, that not only has the philosophical world advanced in knowledge, but in candor, in honesty, and in moral dignity.

The further history of gold, which has assumed a profound interest in modern times, and demands therefore a larger space than is usually devoted to historical notices in this work, will be given in connection with the sources or localities from which it is chiefly derived.

SOURCES.—With the single exception of iron, gold is more generally distributed than any other metal; but for the most part it occurs in such minute quantities, as either to escape notice, or, as already remarked, not to repay the cost of extraction. On the other hand, many localities in different quarters of the globe, and especially, of late years, portions of California and Australia, have proved splendid exceptions. The principal matrix of gold is quartz rock, and this rock is commonly a vein of greater or less thickness, intersecting beds of granite. The chief sources, however, from which gold is obtained, are the various alluvial deposits, consisting of sand and gravel, produced by the disintegration of silicious, granitic, and other igneous and metamorphic rocks, and which have been transported by the agency of water from the mountainous districts. In these beds it is invariably found in the metallic state, but is never quite pure; it usually contains a certain proportion of silver, and not unfrequently iron, copper, and small quantities of several other metals.

It is difficult, if not impossible, to ascertain the precise localities from which were procured the very considerable quantities of gold that indisputably existed in the earlier ages of the world. There is no doubt that many regions, now exhausted, would formerly yield large supplies of this precious metal. The name of the place which figures most prominently in the Old Testament writings, and which has reappeared as the designation of certain auriferous localities, in modern times, is the land of Ophir. This name occurs in the ancient book of JOB, and is frequently alluded to afterwards in the Jewish history. It seems to have been the great source of gold in those days—the California or Australia of the ancient world; but in what country, or even in what quarter of the globe it was situated, is a problem not yet solved. It is certain that the Hebrews traded with it from the time of DAVID to that of JEHO-SAPHAT, and some have placed it in an island in the Red Sea; but this is inconsistent with the recorded fact, that SOLOMON'S fleet took up three years in their voyage to Ophir, and brought home not only gold, but

apes, peacocks, spices, ivory, ebony, and almug-trees. Accordingly, others have removed it to Zanguebar, on the South-east coast of Africa; others have placed it about Guinea; some at Carthage; some have removed it to the East Indies; and others, still more fancifully, to Peru, or some other place in America. The only conclusion which may be safely drawn from this immense variety of conflicting conjectures is, that the question remains involved in uncertainty, although the most general and best supported opinion is that which identifies the ancient Ophir with the region of the modern Zanguebar.

HERODOTUS states that the people living near the source of the Indus, obtained a large quantity of gold from the eastern border of the great Bactriana, and the desert steppes of Cobi; and he also refers to productive mines in the North, the remains of which, on the South-eastern borders of the Ural mountains, are described by PALLAS in his Travels, and were likewise visited by LEPECHIN and GMELIN. These ruined mines, which have all the marks of a very remote antiquity, are supposed to have been the work of a nomadic people, in all probability the Scythians. It is evident that much gold was produced in ancient times from the mines of Nubia and Ethiopia, which, like those of the Uralian chain, produced a copper-yielding gold. BELZONI discovered that a very extensive tract had been worked in the Sahara mountains, and from these sources the PHARAOKS are supposed to have derived their wealth. Mr. JACOB, from a very close examination of the subject, is led to infer that not less than six million pounds sterling of the precious metal must have been produced annually from these mines.

There were rich silver mines in Attica; gold mines in Thrace, and in the island of Thasus. Thessaly produced ores which were rich in gold; and Epirus, rich silver mines. From these sources the Athenians drew their wealth.

The Romans obtained their treasures from various sources, besides the conquered provinces—from Upper Italy, the province of Aosta, the Noric Alps, Illyria. From this district, at one period, gold was abundantly obtained—partly in large grains on the surface, and partly in mines, so pure that an eighth part only was lost in the processes of smelting and refining. Its great quantity caused a decrease of one-third in the price through all Italy, and induced the proprietors to employ fewer workmen in order to raise the value. The Tarbelli, a people at the foot of the Pyrenees, also streamed extensively for gold.

It is stated on the authority of tradition, that when the Phœnicians visited Spain, they found silver in such abundance, that they not only loaded their ships to the water's edge, but made their common utensils, and even anchors, of this metal—a statement which harmonizes with the representations given by the Spanish discoverers of Peru. But whether this account be exaggerated or not, it is certain that the Phœnicians lost no time in taking possession of the country, and forming colonies in the present Andalusia. Now, it is known that Spain anciently possessed mines of gold in regular veins, especially in the province of Asturias. The Tagus and some other streams of that country were

said to roll over golden sands; and there is little doubt, that when colonized by an active commercial people like the Phœnicians, its mineral wealth would be developed, and would contribute largely to the supply of the precious metals in the ancient world.

It is affirmed, that the Romans extracted gold from the quartz lodes in Transylvania, and also at the Ofogan in Caermarthenshire in this island, during their occupation under Trajan. It is probable, however, that but little would be obtained from these sources; and not much further is known of the ancient gold workings.

The principal workings known at the present day are those of Australia, in the Southern hemisphere; of California, Mexico, and the Appalachian mountains, in North America; Brazil, Peru, and Chili, in South America; Kordofan and Sofala in Africa; the Ural mountains in Siberia; and Hungary in Europe. Gold is found, however, in smaller quantities in various other places; and the Editor will now briefly indicate the various localities in which it is known to exist, beginning with Europe, and concluding with the latest discoveries in Australia.

Europe.—There are probably few countries without traditions of gold, and these have not been wanting in the British Islands, which have furnished from time to time small quantities, although seldom in sufficient amount to be equivalent to the cost of procuring it. Specimens are occasionally found in Wales, in the Cornish stream-works, and in different parts of Devonshire; where mining operations were recently undertaken, but not with remunerative success. In Scotland, it occurs at Leadhills and Cumberhead in Lanarkshire, and Glen Turret in Perthshire, but only in very small quantities; although in the time of Queen Elizabeth, extensive washings for gold were carried on in the alluvial soil of Leadhills. In the county of Wicklow, in Ireland, a considerable quantity of native gold was discovered towards the close of the last century, disseminated in a quartzose and ferruginous sand. This gold was chiefly found in *pepitas* or solid pieces, one of which weighed twenty-two ounces; and so promising was the supply, that the peasantry in the neighborhood of Ballinacorney river actually gathered in the course of two months an amount of gold, for which ten thousand pounds sterling were paid. The extraction was then undertaken by Government; but the supply was soon exhausted, for during the two years that the mines were in operation, only nine hundred and forty-five ounces were obtained, which did not pay the necessary expenses, and the works were abandoned.

In France, the Rhone, and other rivers, present auriferous sands, but there are no workable mines in that country. It is probable that the deposits have been exhausted, like those of Spain, which were anciently rich and valuable, but are now neglected. So with the sands of the Danube, and many other European rivers, which still possess gold in small quantities, but rarely worth the expense of washing. In the valley of the Rhine, between Basle and Mannheim, for example, gold occurs in flakes mixed with titaniferous iron; but so minute are the spangles, that it takes from eleven hundred to fourteen hundred of them to weigh a grain, troy. There are also auriferous sands

in some rivers in Switzerland, such as the Reuss and the Aar.

In Sweden, there is a mine at Edefors in Smoland, where the gold occurs native, and also in auriferous pyrites. In Germany, no mine of gold has been worked, except in the territory of Salzburg, amid the chain of mountains which separates the Tyrol and Carinthia. In Piedmont, there are veins of auriferous pyrites in the gneiss rocks at the foot of Monte Rosa; and these, although they do not contain ten or eleven grains in a hundredweight of the ore, are stated to have long defrayed the expense of working them.

But the only gold mines of any importance in Europe, are those of Hungary and Transylvania; and these are not less remarkable for their position, than for the peculiar metals with which the gold is associated. The principal mines are those of Hungary, in which the operations are carried on in four distinct localities; first, at Königsberg, where the native gold is disseminated in ores of sulphide of silver, which occur in veins and small masses in a decomposing felspar rock, constituting a portion of the trachytic formation; second, at Borsan, Schemnitz; and third, at Felsobanya, in both of which the ores likewise consist of auriferous sulphide of silver; occurring, however, in veins of sienite and greenstone porphyry; fourth, and lastly, at Telkebanya, to the south of Kaschaie, where the gold is extracted from a deposit of auriferous pyrites, amid trap-rocks of the most recent formation. The Hungarian gold mines do not appear to have been worked before the eighth century. In Transylvania, the gold occurs at different places in veins of carious quartz, feriferous limestone, heavy spar, fluor spar, and sulphide of silver. These veins are often of great magnitude, averaging from six to ten, and sometimes extending to forty yards in thickness. In the mine of Kapnik, the gold is associated with orpiment in granite, and in those of Offenbanya, Nagy-Ag, and Zalatna with tellurium, in a sienitic rock. The annual produce of Hungary is stated at two thousand eight hundred and ten pounds' weight, and valued at one hundred and seventy-six thousand pounds sterling.

It may be added, that the mines of Reichenstein, in Silesia, which had been abandoned for more than five centuries, have been recently opened with advantage, in consequence of the application, on a large scale, of a method invented by Professor PLATTNER, for separating gold from the waste of arsenical pyrites, which will be described afterwards.

Asia.—The gold mines of Russia, which are the most considerable in the old world, must come under the head of Asia, as they are situated partly on the eastern flank of the Ural mountains, and partly in the districts of Tomsk and Yeniseik in central Siberia. The Ural mines, including those of Berezovsk, near Ekaterinburg, extend through five or six degrees of latitude. Here there are deposits of partially decomposed auriferous pyrites disseminated in veins of quartz; and from these veins the valuable material is extracted by vertical shafts and lateral galleries. Generally, however, the gold is found associated with other metals, as platinum and palladium, in fragments or debris of

auriferous rocks, mixed or disseminated at some yards' depth in an argillaceous loam.

In the days of Pallas, the gold alluvia of Russia were supposed to exist only near Ekaterinburg; but, in the reigns of Paul and Alexander, they were found to extend through several degrees to the North and South of that locality. It was only in the reign of NICHOLAS that portions of the great eastern regions of Siberia were found to be highly auriferous. In these districts the ground rises into low ridges, similarly constructed to those of the Ural, and like them trending from north to south. They are offsets from the great east and west chain of the Altai, which separates Siberia from China. The amount of gold which is now extracted from these remote deposits far exceeds that obtained from the Ural, although, in the latter, sands of superior richness were discovered in 1842. This discovery was made by the removal of certain old buildings in which the washing operations had been carried on. Under the corner of one of the buildings, at the depth of three yards, a mass of gold was dug up weighing about eighty pounds English. This mass was placed in the collection of the Corps des Mines at St. Petersburg. The discovery of the rich sands was made at the same time; but in the Ural districts, the gold is not usually found in large lumps. It is commonly obtained in very small fragments, which are separated by washing; and the yield seldom exceeds thirty-six grains of gold per ton-weight of soil. In the Altai auriferous district, which is represented to be as large as France, not only is the gold found mixed with sand and gravel on the surface, but considerable quantities are extracted by pulverizing the rocks. It is a remarkable fact that, not many years ago, the gold obtained from this distant region did not amount to a third part of that which the Ural district produced, whereas, in 1843, the Eastern tract yielded considerably upwards of two millions and a quarter sterling, and the Ural little more than half a million, raising the total produce of the Russian empire to near three millions sterling. It now amounts to about four millions. In the century previous to 1841, the mines of Berezovsk yielded about twenty-four thousand five hundred pounds avoirdupois of the precious metals.

Little or no gold comes into Europe from other parts of Asia, because, as Dr. Ure justly remarks, its servile inhabitants place their fortune in treasure, and love to hoard up that precious metal. It is evident, however, from the quantities existing in the East, that it must be extracted in considerable amount from various sources. It is found in the rivers of Syria and other parts of Asia Minor. The Pactolus, a small river of Lydia, is said to have rolled over golden sands, which were supposed to have constituted the origin of the proverbial wealth of Croesus. Numerous gold mines are known to exist on the Cailas mountains in the Oundes, a province of Little Thibet, where the gold is found in quartz veins, which traverse a very crumbling reddish granite. It is met with also in the peninsula of Hindostan, and in the islands of the Eastern Archipelago; and it cannot be doubted that considerable quantities are found in Japan and China.

Africa.—It is now the general opinion that the land of Ophir, so frequently mentioned in the Old Testa-

ment, was in Africa, which still presents in one part a territory known as the Gold Coast, implying by its very name the existence of the precious metal in this quarter of the globe. The territory so called, from which large quantities of this metal were formerly exported, lies on the west coast; but the land of Ophir is supposed to have been on the East coast, opposite Madagascar, where a certain amount of gold is still collected. But the principal supplies of this metal are now found at Kordofan, between Darfur and Abyssinia, known to the ancients as Ethiopia, and the western region extending south from the river Senegal to the Cape of Palms, near the Gold Coast. In these districts the gold occurs in spangles, chiefly near the surface of the earth, in the beds of rivers and rivulets, and always in a ferruginous earth. The gold which is brought from Africa is always in dust, showing that the metal is obtained by washing the alluvial soils. Although this division of the globe is supposed to have been the source of the greater portion of the gold possessed by the ancients, yet the whole supply now obtained from that continent is not estimated at more than five thousand pounds annually.

South America.—Brazil furnishes the greatest part of the gold which is brought into the market from South America, and was once the principal gold region of the new world; but its mines and auriferous sands seem to be nearly exhausted. The greatest quantity of gold was obtained from Brazil between the years 1753 and 1763, and since that time it has always been on the decrease. It was in the valley of the Mandi, a branch of the Rio Dolce, at Catapreta, that the auriferous ferruginous sands were first discovered in 1682; but they have since been found widely extended at the foot of the great mountain chain which runs parallel with the coast from the fifth to the thirtieth degree of south latitude. The precious metal is found in nearly all the rivers which form the upper branches of the Francisco, Araguay, Tocantius, and Guaporè; but the largest proportion is found in the affluents of the Francisco. The rock in these localities consists of primitive granite, inclining to gneiss; and the soil, which is of a red, ferruginous character, often extends to a considerable depth. It is from this soil that the gold is extracted by washing. Indeed the veins containing the metal are seldom worked. The most numerous washings are established near Villa Rica, in the environs of Cocães, where the gold occurs either mingled with the sands of the river, or in the alluvial valley deposits. The pepitas occur in various forms, often adhering to micaceous specular iron. In the province of Minas Gerães, the gold is extracted both by the excavation of veins and by the washing of alluvial deposits.

This metal is likewise found in many other parts of South America, on both sides of the great chain of mountains which runs parallel with the Western coast. Peru is richer in silver than in gold ores, but in some parts gold is mined in veins of greasy quartz, variegated with red ferruginous spots, which traverse primitive rocks. All the gold furnished by Columbia, comprehending New Grenada and Venezuela, is the product of washings established in alluvial grounds. But Brazil is the principal gold region of the South American continent.

North America.—More gold is now produced in the vast continent of North America than in any other part of the world. In this respect it has now taken the place which formerly belonged to South America, while the latter has sunk into comparative unproductiveness, less perhaps from the absolute exhaustion of the auriferous soils, than from the want of the capital and enterprise to work them successfully. North America was a gold-producing continent long before the discovery of the Californian treasures; but for many years, the only source of this precious metal in that quarter of the globe was the argentiferous veins of Mexico, from which it was extracted along with the silver, as in the Peru mines of South America. At a later period, however, an extensive gold region was discovered in the United States, extending along the Eastern slope of the Appalachian mountains, from the river Rappahannock in Virginia Southwards to the river Coosa, an affluent to the Alabama, which flows into the Gulf of Mexico. The metal is found in less quantity Northward along the same mountainous range to the State of Maine, and even extending into Canada, where a search for profitable workings has lately been prosecuted with some vigor. The existence of spangles and pepitas of gold, in several rivers of the East of Canada, has been fully established; and at the Great Exhibition honorable mention was made of the Chaudière Mining Company, who exhibited pepitas of native gold, collected in the washing of those streams. But the States of Virginia, North and South Carolina, and Georgia, afford the most productive deposits. In these, as in those of Brazil and Columbia, the auriferous ores are chiefly pyritical; much of the gold is extracted by amalgamation, after stamping under water.

But all preceding gold discoveries in America, or in any other part of the world, were eclipsed by those that have been made within the last few years in California and Australia. These recent discoveries have produced quite a revolution in the annual production of gold, the effects of which, though already powerfully felt in the new impulse given to emigration and commerce, are only beginning to be developed, and must produce the most important results in the future history of the world. This may be inferred from the fact, that the gatherings of the precious metal, reckoning the average produce of all parts of the new and old world for a series of years previous to 1847, did not amount to the annual value of five millions sterling, whereas the amount now exceeds thirty millions per annum.

The first of these recent discoveries was made in 1847, when California, a hitherto-neglected and little-known region, lying at the most remote South-western limit of North America, rose into sudden importance, as the El Dorado of the new world. The gold region, properly so called, occupies the Northern part of California, commencing near the mouth of the Sacramento river, in lat. 39° north, and long. 122½° west, to the north-east of the bay and town of San Francisco, from which it extends south and north. At this point two rivers unite and discharge themselves into the sea—the Sacramento flowing from the North, along a valley formed by mountain ranges, and the San Joaquin, flowing from

the South, along a similar valley, enclosed on one side by the Rocky Mountains, and on the other by the mountainous ridge which protects the Western coast. It was on the property of an intelligent Swiss emigrant, Captain Suter, who had become a wealthy settler on the banks of the Sacramento, that the first traces of gold were discovered in September, 1847. This happened in the course of the erection of saw-mills on the estate, when Mr. Marshall, the contractor for the building of these, observed glittering particles in the sand of the mill-race, which were ascertained to be gold; and on making further researches, it was found that the precious metal was very extensively diffused in the bed of the stream. The discovery soon became known to the work-people, by whom the intelligence was conveyed to San Francisco, and in no long time, the whole population of the little town, and the scattered and scanty settlers in the neighborhood, abandoned their dwellings and occupations to engage in the exciting search. The supply exceeded the most exaggerated accounts that had been given; new and richer localities were discovered; the gold was found in the beds of various streams flowing into the Sacramento; in the mud of the river itself; in the channels of old water-courses, and along the sides of the hills. The intelligence rapidly spread to the neighboring countries—to Mexico, to South America, to the United States, and thence to Europe. People began to flock from all quarters to the once neglected, but now coveted region; it became, in a few short months, the scene of a considerable population, instead of a few scattered tribes of Indians; miners or diggers in parties spread themselves over the face of the country; and San Francisco, from a mere village, grew up into a place of wealth, importance, and stirring activity. It was at first very generally thought that the supply would soon fail, but this anticipation has proved to be unfounded; and while, on the one hand, the amount of the precious metal disseminated in the rocks and soil appears to be almost inexhaustible—on the other hand, the constant increase in the number of miners, combined with the improved apparatus and methods of working, seems to have hitherto resulted in a steadily increasing annual produce, until within the last few years, when it seems to have been nearly stationary.

Professor BLAKE, who minutely examined the auriferous regions of California, states that, with the exception of the diluvial strata, the whole geological formation of the Sierra range, through which flow the principal rivers, consists of igneous and metamorphic rocks. The former are mostly porphyritic in the lower hills, whilst higher up trachytic rocks are more frequently met with. The metamorphic rocks consist of micaeous schists, slates both talcose and micaceous, metamorphic sandstones and limestones, with occasional beds of conglomerate. In that part of the country which he examined, the extent of the diluvial deposits was commensurate, or nearly so, with that of the gold-bearing region. They are found in a belt of land from thirty to sixty miles broad, and running parallel with the axis of the range. These diluvial deposits are met with towards the lower hills of the Sierra, extending frequently some miles into the plain. The elements

of which they are composed differ considerably in various localities, although there are many points of resemblance through the whole series. In the lower valleys and flats, between the ranges of the lower hills, they appear to consist of beds of gravel, containing occasional boulders of quartz and the harder rocks. On the elevated flats, higher up in the mountains, the surface of these deposits is generally covered by a reddish loam, mixed with small gravel; whilst, reposing on the bed rock, and a few inches above it, is found a stratum containing large boulders and gravel, the boulders being principally quartz. At other points, the whole series consists of conglomerates and soft friable sandstone. Where the deposits are found extending over a large surface on the elevated flats, gold is always met with, generally diffused through the gravel immediately above the rock on which they rest, which yields from fifteen to forty cents to the hundred pounds of earth. There are parts where acres of these deposits have been turned up, in which the gravel never contains less than fifteen cents to the hundred pounds, and generally more. In the valleys in the lower hills, and even on the plains to the west of them, where they are extended over vast tracts of country, these deposits are still auriferous, the gold being very generally diffused, and found in greater quantities the deeper they are worked; but sometimes they will not pay for working, owing to the distance from water. In one place, where water could be readily obtained, a portion of these deposits, situated to the west of the lower hills, was found to yield from five to thirty cents to one hundred pounds of earth, through an extent of one hundred and fifty acres, the soil being found richer the deeper it was worked.

At a spot which was appropriately named Mount Ophir, the auriferous soil was described as soft clay and slate, saturated with gold in small particles and large lumps. This treasure was found from ten to thirty feet below the surface, and seven Mexicans, who made the discovery, and kept their secret eight days, made in that short time two hundred and seventeen thousand dollars. Other searchers, from a shaft twenty feet deep, obtained the soft clayey slate in buckets, and found from eight to twelve dollars' worth of gold in each bucket. In many cases considerable nuggets are met with, but no accounts speak of very large masses of gold having been found in California. The total produce from this region, down to the end of 1855, was estimated at sixty-four million pounds sterling; and, latterly, it has averaged about fourteen million pounds per annum.

Australia.—The world-wide excitement created by the gold discoveries in California had scarcely subsided, when another auriferous region was developed in the British dominions at the antipodes, which promises to prove not less productive. The Californian treasures were discovered in September, 1847; and in the spring of 1851 the long-concealed wealth of Eastern Australia was first announced to the world. It is remarkable that this second discovery was not made sooner; for so early as in 1841, the Rev. W. B. CLARKE, in examining the geological structure of the Blue Mountains of Eastern Australia, was attracted by the plutonic and

metamorphic character of the axis of the range, and by the presence of gold in the quartzites, and in the detrital accumulations derived from the axial formations. This gentleman, a native geologist, had found evidence of the existence of gold within sixty and eighty miles of Sydney, and had affirmed his belief that the Blue Mountains would at some time prove to be auriferous. Again, in 1845, Sir RODERICK MURCHISON expressed the same conviction, when he compared the Eastern chain of Australian mountains with the Ural; and in 1846 he even recommended the unemployed Cornish tin miners to emigrate to New South Wales, and dig for gold in the debris and drift of the Australian cordilleras. His writings and remarks on this subject were not entirely without effect, for in 1847 he received letters from speculators in Sydney and Adelaide, accompanied with specimens of gold, which they had sought and obtained, in consequence of his suggestions; and shortly afterwards he even wrote to Earl GREY, informing him that his anticipations were about to be realized in a manner which might operate a great change in the colony.

The discovery was at length made through the instrumentality of a gentleman named HARGRAVES, who had recently returned from California, and had then occupied himself for two months in exploring a considerable extent of country in Australia. On the third of April, 1851, this gentleman addressed a letter to the Colonial Secretary, stating that he had prosecuted his speculation to a successful issue, and offering, for the sum of five hundred pounds, to point out to the officers of Government the localities in which he had discovered gold. To this proposal the Secretary replied that he was not authorized to make a blind bargain, but that if Mr. HARGRAVES thought proper to trust to the liberality of the Government, he might rely on being rewarded in proportion to the value of the discovery. Accordingly, on the thirtieth April, Mr. HARGRAVES addressed another letter to the Colonial Secretary, expressing his willingness to leave the remuneration of his discovery to the liberal consideration of the Government, and naming the localities from which he had obtained specimens of the precious metal. These were at Summer Hill Creek, and other places near Bathurst, which is situated about a hundred and fifty miles west of Sydney, New South Wales.

Scarcely had this communication been made to Government, when the discovery became generally known, through some persons who had been employed under the directions of Mr. HARGRAVES. The fact was divulged that on the eighth of May these persons had obtained several ounces of gold at Summer Hill Creek; and on the thirteenth of the same month great excitement was created by the report that a solid piece, weighing thirteen ounces, had been found. This, on inquiry, proved to be correct, and hundreds of persons immediately left their accustomed avocations, and started for the *diggings*, as they were now called. The excitement rapidly extended, and on the nineteenth of May four hundred persons were congregated at Summer Hill Creek; on the twenty-ninth, one thousand; and on the fifth June their numbers had increased to fifteen hundred.

The Government now lost no time in adopting the necessary measures for maintaining order. A proclamation was issued, dated twenty-second May, 1851, declaring that, from and after the first of June, all persons digging for gold without a license would be proceeded against; and authorising the crown commissioners to grant such licenses for a fee of thirty shillings per month. A force was appointed for the purpose of collecting the fees, and strong detachments of police were stationed along the principal roads leading to the gold fields. At the same time, Mr. HARGRAVES, and the Government geological surveyor, Mr. STUTCHBURY, with whom Mr. CLARKE was afterwards associated, were ordered to make an immediate survey of the various localities in which it appeared probable that gold would be found.

But the spirit of enterprise was now awakened in the diggers themselves, and soon conducted them to new and richer deposits of the precious metal. From Summer Hill Creek, to which the name of Ophir had been given, a great emigration took place to the Turon River—another of the localities first pointed out by Mr. HARGRAVES, and lying a little to the Northward of Summer Hill; and in the month of December the number of diggers on the Turon amounted to six thousand. Subsequently, gold was discovered at various other places in Bathurst, as well as in the adjoining counties of Wellington, Roxburgh, Georgiana, and Ashburnham. Latterly it was found so far South as St. Vincent, and ultimately over the entire mountainous range of New South Wales, extending from 27° to 37° of south latitude; but more abundantly in the Southern portion of the province.

But the progress of discovery did not confine itself to New South Wales. It still advanced to the South; and in a despatch, dated twenty-fifth August, 1851, Lieutenant-Governor LATROBE communicated to Earl GREY, that large deposits had been found in the colony of Victoria. The three localities first named were: Clune's Diggings, about forty miles from Melbourne, where the gold was found in an alluvial deposit, consisting chiefly of quartz gravel; at Buninyong, near Ballarat, about eighty miles from Melbourne or fifty from Geelong, where the gold was sometimes imbedded in compact quartz; and Deep Creek, only nineteen miles from Melbourne, where the precious metal was found to exist in connection with slate rock. It was afterwards discovered almost in the neighborhood of Geelong, and likewise at a place called Mount Disappointment, about thirty miles to the North-east of Melbourne; and, finally, the people of that town began to break up the streets, which had been macadamized with quartz pebbles obtained from the gold districts.

The excitement created in the colony of Victoria by these discoveries surpassed even that which had taken place at Sydney. The whole neighboring population were moving towards the gold regions; Melbourne and Geelong were almost emptied of their inhabitants; and it was found impossible to retain the services of the Government employés, without an addition to their salaries of—first, twenty-five, and, subsequently, fifty per cent. Even the superior class of farmers and tradesmen were drawn into the vortex, partly from sharing

in the general mania, and partly because, when deprived of their laborers and assistants, they had no alternative but the diggings. For some time Ballarat was the great source of attraction, and the stories told of its productiveness were almost incredible. Eight feet square of that auriferous soil was deemed a fortune. One man had found fifteen hundred pounds' worth of gold in one week—another man a thousand. A party of three men had met with twenty pounds' weight in one day!

But even Ballarat was shortly surpassed by a fresh gold-field discovered in the Mount Alexander range, still further to the north, about ninety miles from Melbourne. This was found to exceed in richness all the diggings previously discovered. So great were the attractions of this new field, that the number of diggers at Ballarat, which had risen to six thousand, was quickly reduced to one thousand six hundred, while the number at Mount Alexander rose to twenty thousand. This was the climax of the excitement created by the gold discoveries. The whole structure of Australian society became for a period completely disorganized. Subsequently the precious metal was discovered at various other localities, and the supply was so far increased that gold arrived at the seaports at the rate of two tons per week. The excitement has now subsided; and no new localities have been reported, yielding the same fabulous treasures as Ballarat and Mount Alexander, when first discovered; but various new sources have been opened up, and a map of the country, exhibiting the gold regions, seems to indicate the precious metal as disseminated in greater or less abundance over the whole of the mountainous range which extends through New South Wales and Victoria. The field of operations, therefore, continues to extend; improved machinery is brought into action; and the consequence is, that, while less excitement exists, there is more of steady productive labor, and the aggregate supply of the precious metal has continued to increase yearly till the present time, when it seems to have attained nearly its maximum, at thirteen millions per annum. It is expected, however, that when the labors of the large numbers now employed in deep sinking and in quartz mining are brought to a profitable consummation, the yield, if not greatly increased, will at least be permanently sustained. Further details on this subject, and the produce of the principal mines and auriferous regions throughout the world, will be given at the close of the present article, under the head of Statistics.

ORIGIN AND POSITION OF THE GOLD DEPOSITS.—The matrix of the gold in Australia, as in other auriferous regions, is quartz. The general character of the soil may be inferred from the description given of the Turon and Summer Hill Creek districts, where the gold was first found, and where, according to Mr. STUTCHBURY, the Government geologist, the whole area may be considered as schistose, principally clay-slate, accompanied by nearly all the other varieties of slate rocks, and also by a large amount of quartzites in veins or lodes, parallel to the stroke of the schist. In this district, the trend of all the waterways, or *creeks*, in which the gold is chiefly found, is into the Macquarrie river. The

quartz is amorphous, very rarely crystallized; and in the neighborhood of the gold-yielding localities, it is accompanied by titaniferous iron, both crystallized and in loose grains. Many instances occur in which the quartz remains attached, and interlaced by the gold, as also the iron. It is a fact worth recording, that no gold has been found in Australia, without the iron sand—incorrectly termed *emery*—accompanying it.

Gold in small quantities has been found on the summits and upon the flanks of the mountain ranges; but, with few exceptions, it bears evidence of abrasion; and the larger produce in every instance has been found in the lower levels. Assuming that the auriferous deposits originated in the quartz rock, says Mr. STUTCHBURY, there is no difficulty in accounting for its presence most abundantly in the various gullies and creeks so numerous in this remarkably broken country. The schistose rocks, so readily acted upon by the atmosphere, constantly disintegrating and exposing the quartzose dykes, leave them unsupported; and gravitating downwards, the largest blocks are crushed and crumbled in their onward course, letting loose the tenacious gold in large or small portions, which, in obedience to their gravity, and the force of the impelling torrents, roll on until they are arrested for a time in hollows, or the cleavage fissures of the slaty rocks, or quietly deposited in the sand and mud, as the case may be, by the cessation of the flood, until they are again removed by the repetition of similar causes; or they may remain for ages undisturbed, by the torrents taking another course, of which there are so many instances, leaving ancient bars of shingle debris now covered by accumulated soil. It therefore follows that gold, even if it be of the earliest geological origin, may and will be accumulating in the lower valleys, as long as mountains waste and valleys exist for its reception.

It has been asserted, however, by some writers, that the gold, instead of being torn out by the waters from the veins and primitive rocks which they traverse, actually belongs to the grounds washed by the waters as they glide along. In proof of this, it has been urged that gold is almost always found among the sands of rivers only in a very circumscribed space, and that on ascending these rivers, their sands cease to afford gold, whereas, did this metal come from the rocks above, it should be found more abundantly near the source of the rivers. Thus, the late Dr. URE remarks, that the Orco contains no gold except from Pont to its junction with the Po. In like manner, the Ticino affords gold only below the Lago Maggiore, and consequently far from the primitive mountains, after traversing a lake where its course is necessarily slackened, and into which whatsoever it carried down from the mountains must have been deposited. The Rhine gives more gold near Strasburg, than near Basle, though the latter be much closer to the mountains; and the sands of the Danube contain no gold, so long as the river runs in a mountainous region—that is, from the frontiers of the Bishoprick of Passau to Efferding—but they become auriferous in the plains below. The same thing is stated of the Ems, and other rivers; and it must be admitted that the opinion, to which it naturally leads,

rests upon very strong grounds, and is supported by some of the highest authorities.

Though gold is frequently found at the surface, mixed with the sands of rivers, yet the auriferous stratum is often buried at considerable depths, and hence the necessity of opening *pits* or *diggings*. Figs. 204 and 205 will afford some idea of the Australian gold-field strata. The latter represents what the diggers call a surface gullet, the gold being met with at about sixteen feet from the surface; the former is a

Fig. 204.

Fig. 205.

section of a deep gullet, in which the auriferous ore is at a depth of thirty-six feet. The corresponding letters, in both sections, indicate similar strata; *a*, black loam and quartz; *b*, white loam, clay, and sand; *c*, brown clay; *d*, gold layer; *e*, yellowish-brown rock; *ff*, quartz in a concrete mass; *g*, stratum of sand; *h*, common clay. The auriferous ore earth is generally of a light color, or largely mixed with quartz pebbles, very tenacious and difficult to wash. It lies upon a yellowish brown rock, of a rotten texture, known as fixed slate, whilst higher up, above the gold, the strata present igneous features.

Probable abundance of Gold at great depths.—The probability that gold exists in almost unlimited amount at greater depths than have been yet explored for this metal, is thus argued by Mr. W. BRIDGES ADAMS: Quartz rock is the matrix of gold, and quartz rock is commonly a vein of greater or less thickness intersecting the beds of granite. In this quartz the metallic gold is distributed, in particles of more or less fineness, and sometimes it is found in lumps. If the granite be supposed to have been once in a state of fusion, and cracked in cooling, forcing up into the fissures the liquid quartz containing the gold, it seems more than probable that the greater part of the molten gold would settle to the bottom of the fluid mass, as the metal precipitates in an iron furnace, beneath the slag. The fragments that are found in rivers and alluvial ground have probably been thrown out by subsequent volcanic action. The spangle-gold, the nuggets, the gold-dust, and other varieties, seem to confirm this; and probably, in depths of alluvion greater than have yet been penetrated, large golden fragments will be discovered, just as the hugest pieces of rock are found undermost in the beds of mountain torrents. If this theory be correct, it is quite within possibility that the gold-hunters, who have as yet explored but a small portion of the earth's surface, may light upon larger deposits—may yet penetrate to some mass larger than the famed native iron of Santiago del Estero, or a quartz vein gradually changing into the

pure metal. The lighter fragments washed to the edges by the stream have alone been gathered; they are but indications of the larger masses that lie in deposit below; and it may be predicted that wherever gold has been superficially gathered at any period, it will be found in larger masses at some greater depth.

If there be any truth in this ingenious conjecture, it will soon be brought to the test of experiment by the operations now in progress in Australia, with a view to deep sinking and quartz mining on a very extensive scale.

METHOD OF EXAMINING AURIFEROUS DEPOSITS.—

As a general rule, the rocks in the district to be examined for gold should be either granitic, porphyritic, or quartzose, although it is also found in other formations, and particularly in clay-slate. The auriferous quartz is often stained of a rusty brown color, from the presence of peroxide of iron, and in many instances presents a cellular or honeycombed appearance. The points to be most carefully examined are the sands of the rivers and streams, or old water-courses, as well as the particles of disintegrated rock which often accumulate in the eddies of ravines formed on the sides of hills by the action of water during great floods. The sections of rock exposed by this action must also be examined with a view to the discovery of veins of auriferous quartz, from which specimens are broken off and afterwards carefully assayed.

The method of conducting a systematic assay of gold ores and alloys will be fully explained afterwards. It is a somewhat tedious and difficult process, requiring considerable experience and a regular assortment of apparatus. But even in the absence of these, a tolerably correct estimate of the amount of gold present may be readily arrived at by the following simple method.

The fragment of rock, supposing the ore to be quartz, is first pounded very fine and sifted, a portion of the sand or powder thus obtained is washed in a shallow pan, and, as the gold sinks, the lighter portions of the substance are allowed to float off. The greater part of the gold is thus left in the angles of the pan; and by adding more of the powder, and repeating the same process, a further portion is obtained. When the bulk of powder, with which the gold is mixed, is thus reduced to a manageable quantity, mercury is added to the mass, and forms with the gold an amalgam, which is afterwards heated in an iron retort to expel the mercury. In this way the proportion of gold contained in a specimen of rock may be ascertained with considerable exactness. The sands brought down by rivers are examined in much the same manner, but do not require the previous pounding; and a fair estimate of their value may be generally formed without the amalgamating process. Sometimes, indeed, the gold may be present in considerable quantity, although in a state of division so minute as not to be readily perceived by the unassisted eye, and, therefore, in examining the earthy residuum, a small magnifying lens will be found of great use.

It is generally considered that the sand of any river

is worth working for the gold it contains, provided it will yield twenty-four grains to the hundredweight; but the sands of the African rivers often yield sixty grains in not more than five pounds weight, which is in the proportion of more than fifty times as much, while the Australian rivers have been known to yield considerably more.

SUBSTANCES OFTEN MISTAKEN FOR GOLD.—

Though gold, in its separate and pure state, is readily distinguishable from other metals and minerals, by its color, softness, high specific gravity, and insolubility in the simple acids, yet in the mixed state in which it is generally found it requires an amount of chemical skill to apply these tests, and hence, where glittering particles of other minerals appear, they are often mistaken for gold, even by persons who are not entirely ignorant of its characteristics. The substances which most generally lead to this mistake are iron pyrites, copper pyrites, and yellow mica.

Common iron pyrites, or bisulphide of iron, which is more frequently mistaken for gold than any other substance, occurs in small cubical crystals, in veins disseminated in the various slate rocks, and in the coal measures. It is of different shades of brass-yellow, and often in fact contains minute traces of gold, though seldom a sufficient amount of that metal to render its extraction profitable. It may be readily distinguished from gold by the application of the magnet, as well as by the following characters: first, instead of flattening like gold under the hammer, it is extremely brittle, and, therefore, readily broken; second, its weight or specific gravity is only about one-fourth that of gold; and lastly, when heated with nitric acid it is dissolved with evolution of copious red fumes, whilst gold, when so treated, remains unaffected. It was only recently the Editor was consulted by a gentleman who imagined he had discovered a gold mine in Ireland. The sample brought turned out to be a fine specimen of sulphide of iron embedded in quartz.

Copper pyrites, or yellow copper ore, the second mineral which is frequently mistaken for gold, is a ferrosulphide of copper, and may be considered as a compound of two equivalents of sulphide of iron, and one equivalent of sulphide of copper. This is the ore from which the largest proportion of the copper of commerce is derived. It occurs in a variety of forms, its primitive crystal being the regular tetrahedron. It is formed in lodes or veins, which usually occur either in granite, grauwacké, or clay-slate, and has a strong metallic lustre, and deep brass-yellow color. It may readily be distinguished from gold by the circumstance, that when heated on a piece of charcoal before the blowpipe it loses this yellow color, and fuses into a dull black globule, which, from the presence of the iron, is magnetic. If mixed with carbonate of soda and a little borax, it yields, when similarly treated, in skilful hands, a button of metallic copper. But an easier method to determine the presence of copper is to pulverize the ore in an iron mortar, or with a heavy hammer, dissolving the powder thus obtained in nitric acid, and evaporating the solution nearly to dryness; water is then added, and afterwards ammonia in excess, when, if copper be present, the liquor assumes a rich pur-

plish color, an unmistakeable sign of the presence of copper.

Another method for determining the presence both of iron and copper, is to take some of the scoria left after submitting it to the blowpipe, and, putting this in a test-glass, to pour over it a few drops of hydrochloric acid, when an effervescing solution will be obtained. A little of this liquid is then transferred to another glass—the one to be treated for iron, the other for copper. Into one of the glasses introduce a few drops of ferro-cyanide of potassium, and liquid ammonia into the other. If iron is present, the liquid in the glass to which the ferro-cyanide has been added will become blue, the iron combining with the ferro-cyanogen, and producing Prussian blue. If copper is present in the same glass, but no iron, the liquid will become of a reddish-brown tint, ferro-cyanide of copper being formed. If iron and copper are present together, the two metallic precipitates will be the result, and a purple tint arises from the mixing of the red and blue colors. The liquid in the glass to which ammonia was added will be changed to a brownish tint if iron is present, and to a fine blue if copper is there.

Mica, the third substance often mistaken for gold, is one of the constituents of gneiss granite and mica slate, and gives to the former its lamellar structure. In 1853 great excitement was produced at the Cape of Good Hope, in consequence of the discovery, near Simon's Bay, of a substance said to contain a large proportion of gold. A quantity of this suspected mineral was sent home for analysis, and was found to possess a glistening, yellow, semi-metallic lustre; but when submitted to the searching powers of the microscope, its metallic brilliancy disappeared, especially when viewed by transmitted light. It had then a darkish-grey color, being in thin semi-transparent plates. It was not acted upon by nitric or nitro-hydrochloric acid; and hence, doubtless, arose the error in taking it to be gold. In reality, it was nothing but mica, highly colored with the oxide of iron, and yielding, on analysis, the following constituents:—

	Centesimally.
Silica,	46
Alumina,	23
Potassa,	14
Oxide of iron,	16
Manganese,	1
	100

The specific gravity of mica never exceeds 3·00; and this circumstance, together with its foliated structure, is quite sufficient to distinguish it from gold, which it somewhat resembles in color; but even in this latter particular, the microscope will dispel the illusion.

CHARACTERS OF NATIVE GOLD.—Gold, as already stated, almost always occurs in the metallic state, generally in small grains or scales known as *gold dust*, sometimes in particles so minute as to be invisible, but occasionally in pieces of considerable weight, termed *nuggets*. It appears doubtful, indeed, whether, when this metal occurs in pyrites, it exists in every instance in minute metallic particles, or whether, in some cases at least, it may not be present in combination with sulphur. The auriferous pyrites, as DUMAS remarks, con-

tain the gold disseminated through their mass in such small quantities, that it is almost always impossible to ascertain, even with the aid of the microscope, in what state the precious metal exists. As a preliminary roasting of this auriferous ore is generally useful, with a view to the subsequent amalgamation, a doubt may be entertained whether it is really present in the metallic state, though this has been generally assumed hitherto. But DUMAS thinks that the powerful electro-negative tendency of sulphide of gold affords a strong presumption in favor of the hypothesis, that this metal may exist partly, or even entirely, under the form of a double sulphide, in iron and copper pyrites, *et cetera*. BROGNIART observes, that it is chiefly in its association with these sulphides, as also with galena or sulphide of lead, blende or sulphide of zinc, and mispickel or arsenical pyrites—a sulphide of arsenic and iron—that the gold becomes invisible to the eye, a circumstance which is justly regarded as strongly confirming the opinion expressed by DUMAS. The other minerals with which it is found associated are grey cobalt, lithoidal manganese, native tellurium, malachite, sulphide of silver, red silver, and sulphide of antimony.

When the gold is found in the form of nuggets, these generally communicate the impression of their having been melted; and in many newspaper accounts, and

Fig. 206.

letters received from the diggings, the gold is described as having been evidently in a state of fusion, and as resembling drops of melted metal poured into sand, the indentations being visible even upon the smallest particles of the gold when microscopically examined. It is certain that such indentations may be observed in most

specimens, as indicated in Fig. 206, which exhibits a microscopic view of a fragment of Australian gold magnified seven hundred times. Mr. J. B. JUKES, however, who may be regarded as a competent authority, conceives that this is probably a mistake, and that the idea may have originated from the gold having been deposited in small holes, crevices, and interstices of the quartz rock, and subsequently rolled, so that it assumes such forms as melted lead is seen to do. It does, certainly, appear remarkable that the particles of gold should retain indentations received in a state of fusion, after being tossed about, probably for a long period, among water and gravel.

Fig. 206 has been given as the greatly magnified representation of a very small grain. Fig. 207, on the contrary, is a much reduced delineation of a lump of almost pure gold, weighing 27 lbs. 6 oz. 15 dwts, which was found in the diggings, at Forest Creek, Mount Alexander, in the Colony of Victoria. Among other pieces brought home with it in the same vessel, were several nuggets weighing upwards of a pound each,

and one of 1 lb. 8 oz. 6 dwts. These smaller lumps, however, contained quartz, whilst the larger one appeared a massive lump of nearly pure gold, of a very fine color. It measured eleven inches in

Fig. 207.

length by five in breadth, at the widest part. This was supposed to be the largest nugget which had been found in Australia up to the time of its discovery, but one or two others considerably larger have been since obtained.

Gold is also occasionally, though rarely, found in a crystallized state; and when met with, the crystals should be carefully preserved as cabinet specimens, for which purpose their value is much greater than that which they are intrinsically worth for the gold they contain. The most common forms are the cube and octahedron, with their various modifications. The faces are generally dull, and in most instances the edges are slightly rounded. Some years ago, several interesting specimens of crystallized gold, from California, were described in *Silliman's American Journal*, by Mr. FRANCIS ALGER of Boston. The collections in which the specimens were found were brought from California by Mr. G. E. TYLER of Boston, and Mr. H. B. PLATT of New York. The crystals were distinctly octahedral, simple and modified, the surfaces being but slightly disfigured by attrition, or the effects of transported action—a very unusual circumstance, as gold is generally found in comparatively minute grains, at a distance from the rocky matrix in which it is supposed by some to have been primarily embedded. Mr. ALGER states in his paper, which was read before the Boston Society of Natural History, that he had never before seen what was unquestionably a genuine crystal from California. He adds that an irregular crystalline plane could only occasionally be traced out in former specimens; but among those exhibited were examples of crystallization as perfect, among the small ones especially, as are to be seen in magnetic iron ore or in spinelle.

Of the larger specimens in these collections, the most striking examples were three octahedrons of the sizes exhibited in Figs. 208, 209, 210. Each of these crystals was found in an isolated state. The smallest one—Fig. 208—was the most perfect, and was entirely free from any adhering portion of the matrix. This unusually perfect crystal exhibits, as partly shown in the Figure, four pretty regular faces in the lower half, and three of its six solid angles are perfectly formed to a point. Two of its faces are sunk or depressed; and in one of them, the cavity thus formed, is very deep and regular, like an interior triangle; the depression extend-

ing not quite to the edges, but so as to leave all round a narrow ridge or border, the interior sides of which are parallel with the edges of the crystal. Mr. ALGER in-

Fig. 208.

Fig. 209.

Fig. 210.

ferred that this depression, which is shown by a darker shade in the wood-cut, had been formed when the crystal was in a liquid state, and that, soon after the outside had congealed or solidified, the inner portion, or a part of it, had run out, leaving the surrounding consolidated edge in a perfect form. He remarks that he has seen something similar to this formed among artificial crystals, as, for instance, metallic lead—which takes the form of an octahedron—and lead ore partially desulphurized, when the metal was allowed to flow off slowly, just as the outer crust had formed over the surface of the crystals. Indeed, this parallel case is of not unfrequent occurrence in the crystallization of the ductile metals.

In the largest—Fig. 209—of the three crystals of which the preceding sketches are given, it will be observed that only one-half of the octahedron is formed, its base blending with the rough gold, or showing only the commencement of the planes of the upper pyramid. Three of the planes are quite smooth, except along their edges, which are permanently marked by the same projecting border or edge described on the smaller crystal. The depression, however, is not so great as in the latter. Mr. ALGER remarked that this peculiarity was confined to the unmodified crystals.

In some there was a double series of these ridges, the inner one appearing to exhibit the commencement of another crystalline face within the cavity of the larger one. This phenomenon was strikingly shown in a crystal represented of the natural size in Fig. 210.

The two larger crystals—Figs. 209 and 210—were obtained from the collection of Mr. PLATT, who resided a couple of years at San Francisco, and being in a situation which brought him into constant intercourse with persons returning from the mines, purchased, at no small expense, the most interesting specimens he could find. His collection was described by Mr. ALGER as of singular beauty and value, comprising a great variety of ramified, arborescent, dendritic, and other imitative forms, all of them, sometimes, fantastically joined together in the same specimen. In obtaining his valuable collection, he had examined gold to the amount of more than four millions of dollars. The remarkable size of the two larger crystals thus described, and the fact that some of the others contained portions of oxide of iron, induced a suspicion that the greater part of them were pseudomorphs of sulphide of iron; but Mr. ALGER believed that they were formed

VOL. II.

under the ordinary circumstances of crystallization, either in an open space, or while surrounded by a matrix, in such a fluid state as to allow them full freedom to take their natural form. His reasoning on the subject, if not perfectly conclusive, leads to a strong presumption in favor of the octahedron as the primary form of gold; and if this were more generally known, much disappointment and trouble might be saved in cases where sulphide of iron and other crystalline metallic forms are mistaken for the precious ore.

In Mr. TYLER's collection, Mr. ALGER found several rare modifications, some of them resembling those which come in their most perfect forms from Brazil. Fig. 211 exhibits in three positions, *a*, *b*, *c*, a compound form produced by the union of two opposite segments of an emarginated octahedron. Fig. 212 is a modifi-

Fig. 211.

cation of the same form, though apparently consisting of irregular six-sided tables, with truncated edges. Some of the unmodified macles, as shown in different positions, in Fig. 211, were stated by Mr. ALGER to be very distinctly formed, the edges between *ee*, uniting the two segments of the octahedron, being well

Fig. 212.

Fig. 213.

Fig. 214.

defined. This is very strikingly shown in Fig. 213, in which the crystals are exhibited as magnified to twice their natural size. Fig. 214 shows the opposite side of the same specimen, connected with two other crystals, one a very beautiful and smooth-planed octahedron with emarginated edges.

Fig. 215 exhibits a macle of gold which came from Malto-Grosso in Brazil, and is in the collection of the School of Mines, Paris. It is similar to that represented in Fig. 211, from which it only differs in exhibiting more of the planes of the octahedron and dodecahedron. This figure is copied from the volume of crystallographic illustrations accompanying M. DUFRÉNOY's treatise; but besides conforming his lettering to the notation of PHILLIPS, those are made primary planes which are given by DUFRÉNOY only as secondaries of the cube.

Fig. 215.

In all these the octahedral form is manifest, which may therefore be assumed to be the form natural to gold when its particles crystallize in cooling; but as nearly all of these crystals show the effects of abraded action, it is often difficult to distinguish planes confined within such narrow limits, and which are too small or too rough to admit of accurate admeasurement. Indeed the faces of the crystals are in most instances slightly rounded, even in specimens obtained directly from veins, and which, consequently, cannot have been exposed to attrition.

COMPOSITION OF NATIVE GOLD.—Native gold is never quite pure, being almost invariably alloyed with silver, and containing frequently small proportions of copper and iron. In Siberia it is often associated with platinum, and in the Gongo Soco mines in Brazil, an alloy of gold and palladium of a pale yellow color is sometimes found. In Columbia a somewhat similar

mixture is procured, in which the palladium is replaced by another rare metal called rhodium. In Hungary it is met with in combination with tellurium and other elements. The specific gravity of native gold varies from 13.3 to 18.5.

The proportion of silver, the principal ingredient which is found in combination with gold, varies from one to fifty per cent.; and not only differs greatly in specimens of native gold obtained from diverse regions, but even to a certain extent in specimens from the same auriferous district. In general, however, the composition of the gold of the same district is remarkably constant; so much so, that the knowledge of the locality whence it is derived is often sufficient to enable the experienced assayer to guess pretty nearly the quantity of pure gold which the compound contains. The subjoined table presents the composition of native gold from various parts of the world:—

SIBERIA AND URAL.					
Locality	Authority	Gold.	Silver.	Copper.	Iron.
Schabrowski,	Rose,	98.96	0.16	0.35	—

Wicklow,	Mallet,	92.32	6.17	—	0.78

From this table it will be seen that the gold both of California and Australia contains silver, but that the specimen from the latter was remarkably pure; and such, indeed, is the general character of Australian gold. Neither platinum nor palladium, nor any trace of the metals of that class, is found in the newly discovered gold regions. There is, however, a trace of iron in the Australian specimen, and a small proportion of both copper and iron in those from California.

PREPARATION OF PURE GOLD.—Like native gold, that which is used in the currency, as well as in the manufacture of jewellery, is never absolutely pure, being always alloyed with some other metal, such as copper or silver, to give it the requisite hardness. The proportions of the metals which enter into these alloys will be afterwards stated. The methods adopted, also, for obtaining pure gold on the large scale, or, in other words, the metallurgical treatment of gold ores, with a view to the extraction of the precious metal in a state of purity, will be fully explained. In the meantime, it may be desirable, before proceeding further, to show

how a small portion of pure gold may be prepared in the laboratory.

For this purpose, a piece of native gold, a small quantity of gold dust, or a few coins or fragments of old jewellery are dissolved in nitro-hydrochloric acid—the *aqua regia* of the alchemists—consisting of four parts of hydrochloric with one of nitric acid. This will give a solution of terchloride of gold, mixed with chloride of silver, if any of that metal be present. The solution thus obtained is evaporated with an excess of hydrochloric acid for the purpose of destroying the excess of nitric acid. The residue is then treated with hot water, by which it is dissolved, with the exception of the chloride of silver, from which the solution is decanted or separated by filtration.

An excess of protosulphate of iron in solution is then added to the auriferous solution in the proportion of four or five parts of the crystallized protosulphate—green vitriol—to one of gold; and the mixture is put in a warm place, and allowed to stand for several hours. In the reaction which occurs, the chlorine that was combined with the gold unites with a portion of

the iron of the protosulphate, part of which is thereby converted into sesquisulphate, while sesquichloride of iron is at the same time formed, and metallic gold is precipitated. This reaction is represented in the annexed equation:—

To precipitate the gold from an acid solution of its chloride, LEVOL prefers to the protosulphate of iron an acid solution of terchloride of antimony, in which case the following equation exhibits the reaction that takes place:—

In this case, if chloride of silver be present, it is retained by the hydrochloric solution.

The precipitated gold is in the form of a finely-divided powder, which, when suspended in water, is brown by reflected and purple when viewed by transmitted light; but under the burnisher it readily assumes the metallic lustre and characteristic color of malleable gold. It also admits of being aggregated and welded together by percussion; and if heated to whiteness, and in that state struck repeatedly with a heavy hammer, its particles become united into a solid mass, without having been raised to the point of fusion.

To obtain the gold in a perfectly pure state, however, the precipitated powder is boiled with hydrochloric acid of specific gravity 1.1, which is then decanted, and the residue is boiled twice with fresh acid. The gold is *not* washed between these successive treatments with acid, which remove the last traces of iron, and nearly all the chloride of silver.

Lastly, the gold is well washed, dried, and mixed with its own weight of bisulphate of potassa, or a small quantity of borax and nitre, and fused in a Hessian crucible exposed to a very strong heat. By this operation, the last portions of chloride of silver are removed, and a button of perfectly pure gold is obtained.

PROPERTIES OF PURE GOLD.—Pure gold is of a rich reddish-yellow color, and high metallic lustre; in the pulverulent state it is brown and dull, but acquires, as has been stated, the metallic lustre by pressure. The specific gravity of fused gold is 19.2; of hammered gold, from 19.3 to 19.4. In this respect, therefore, it stands only second to platinum, of which the specific gravity is about 21.5. Finely-divided gold, precipitated by sulphate of iron, was found to vary in density from 19.55 to 20.72; and when precipitated by oxalic acid, its density was 19.49. Its equivalent is 197. In a pure state it is softer than silver, and nearly as soft as lead; but its tenacity is so great that it may be drawn out into very fine wire; and such is its malleability that it may be hammered out into leaves only one three hundred and seventy thousandth of an inch in thickness. A single grain may be extended over 56.75 square inches of surface, or drawn out into a wire five hundred feet long. RÉAMUR, by rolling out a fine gilt silver wire, reduced the coating of gold to the twelve-millionth of an inch in thickness, and the surface appeared to be perfect when viewed under the microscope.

Gold does not combine directly with oxygen, and,

therefore, suffers no change by exposure to air and moisture at any temperature—not even by being kept in a state of fusion in open vessels. It is not attacked by the mineral or any of the simple acids, except selenic, and this by the aid of heat. The alkalis do not affect it, and hence a crucible of gold is a valuable instrument in the analysis of minerals which require fusion with the caustic alkalis. It is not acted on by sulphur, and, consequently, sulphide of hydrogen is not decomposed by it, as in the case of silver. Iodine has only a weak action upon it, but bromine and chlorine attack it easily at ordinary temperatures; and it is dissolved by any substance which liberates chlorine. It is therefore dissolved by hydrochloric acid, if binocide of manganese, chromic acid, *et cetera*, be added thereto. Its usual solvent is that already stated—a mixture of one part of nitric acid, and four parts of hydrochloric acid. *The proper solvent of gold is nascent chlorine*, which is eliminated by the mutual action of the mixed acids.

Gold is one of the most perfect conductors both of heat and of electricity. It fuses at a bright red or a white heat, the temperature of which has been estimated at 2016° Fahr. It is therefore less fusible than silver or copper, the former fusing at 1873°, and the latter at 1996°. In fusion it exhibits a bluish-green color. It is not sensibly volatile in the strongest heat of a blast furnace; but in the focus of a large convex lens, in the intense heat of the oxyhydrogen jet, or under the influence of a powerful electric discharge, a gold wire is dispersed in vapor; and if, in the latter case, the wire be placed just above the surface of a sheet of paper, the course of the discharge is marked by a broad, dark, purple stain, produced by the finely-divided gold. If, instead of the sheet of white paper, a plate of polished silver be employed, it is traversed by a brightly-gilded line, which is firmly attached to its surface. When a globule of gold is placed between the terminal charcoal points of a powerful voltaic battery, it enters almost immediately into fusion, and gives off abundant metallic fumes.

Gold contracts on cooling, and cannot be advantageously employed for castings, as it shrinks greatly at the moment of solidifying. GRAHAM states that it cannot be obtained in crystals by cooling; but according to other authorities, when large quantities of gold have been fused, and are then allowed to cool slowly, cubes more or less modified on their edges and angles are frequently the result. It has been shown that native gold affords numerous well-defined crystals belonging to the cubic system, and that of these the greater number, if not all, is affected by the faces of the regular octahedron.

CHEMICAL EXAMINATION OF GOLD ORES.—A rude method of ascertaining the presence of gold in crushed quartz, or earthy ore, by washing with the hand-basin, has been described; but gold is often present in the matrix in grains or particles so minute that it cannot be detected by the eye, and sometimes it is quite disguised by admixture with other metals or minerals. Many cases occur, however, in which it is of great importance to ascertain the presence of gold, not only as a first step in the examination of suspected auriferous ores, but likewise in the assaying of alloys of gold with dif-

ferent metals. In commencing mining operations, the fact of the *presence of gold* in the ore, in any appreciable quantity, is the first point to be determined; and if this be decided in the affirmative, the next point is to determine the *proportion or quantity of gold* contained. The first process is termed *testing for gold*, or the *qualitative examination* of a suspected mineral; the second is the *quantitative examination*, or *assaying process*.

Sulphate of iron, protochloride of tin, and oxalic acid are the tests or reagents pre-eminently employed in seeking to determine the presence of gold.

Before any of these tests can be applied, the substance supposed to contain the gold must be brought into a state of solution; and this can only be done by means of the mixture of nitric and hydrochloric acids already mentioned. If the substance consist of earthy or quartzose matter, this must be reduced to powder by trituration in a mortar before it is subjected to the action of the solvent; but if the matter under examination be simply a metallic alloy, it can be dissolved without any previous preparation. An excess of acid should be avoided, and for this purpose some carbonate of soda should be added. When the solution is effected, the liquid should be evaporated to about one-eighth of its original bulk, and then diluted with three or four ounces of water. The action of the reagents is as follows:—

1. *Sulphate of Iron or Green Vitriol*.—If a few crystals of this salt be dissolved in distilled water, and dropped into the suspected solution, the result is the precipitation of the gold, if any be present, in the form of a dark-brown powder, which is metallic gold in a very fine state of division, as already described in connection with the laboratory process for preparing pure gold. If the solution has been mixed with a considerable quantity of water, the liquid, on the addition of the green vitriol, is colored brown by reflected, and blue or a dingy green, by transmitted light; and this is obvious even when forty thousand parts of the menstruum are present to one part of gold. If the liquid amount to eighty thousand parts, it is colored sky-blue; with one hundred and sixty thousand parts, it becomes violet; with three hundred and twenty thousand parts of liquid, the violet tint is still very obvious; but with six hundred and forty thousand parts, it is with difficulty perceived.

The deposit formed when the sulphate of iron is added may be corroboratively proved to be gold, by its being insoluble in nitric acid, but readily soluble in aqua regia.

2. *Protochloride of Tin*.—If to another portion of the nitro-hydrochloric solution be added a small quantity of a solution of protochloride of tin—commonly known as *salts of tin*—there will be immediately produced, if any gold is present, a dark brownish-purple precipitate, known as *purple of Cassius*. This substance is used in enamel and porcelain painting, and also for tinging glass of a fine red color, in connection with which applications it will be noticed afterwards. Its color, though not a brilliant purple, but rather a reddish-brown, is characteristic, and after being once seen is not likely to be mistaken. Its appearance, when the chloride of tin is added to the liquid, affords

an infallible proof of the presence of gold, for a very minute portion of that metal gives a manifest reaction when this test is employed.

When the first test—sulphate of iron—has been applied, and its evidence corroborated by the solution of the precipitated gold powder in aqua regia, the protochloride of tin may be employed to produce the purple of Cassius in this solution also.

3. *Oxalic Acid*.—This substance, either in crystals, or dissolved in water, causes, when added to the nitro-hydrochloric solution, the precipitation of any gold that may be present, in the form of a brown or greenish-black powder, in the same manner as the sulphate of iron; but the precipitation does not occur so rapidly. Indeed, it requires not less than forty-eight hours for the whole of the gold to be thrown down by the oxalic acid, unless heat is applied, by which the process is accelerated. The precipitate is pulverulent gold, and may be tested, as in the first case, by its insolubility in nitric acid, while readily dissolving in aqua regia. A crystal of oxalic acid, wetted with a solution of gold, becomes soon covered with a thin film of the metal, having its distinctive color and lustre.

These are the tests most easily applied by persons unaccustomed to chemical manipulation. At the same time, it may be useful to know the reactions of gold with various other substances, the most important of which, including the three already mentioned, are summarily tabulated as follows by Dr. LYON PLAYFAIR, in a lecture delivered by that chemist at the Museum of Practical Geology:—

TESTS FOR GOLD.	
Tests or reagents.	Results.
Sulphate of iron,.....	In acid solution, brown precipitate; if very dilute solution, only a blue coloring.
Protochloride of tin,.....	In dilute solution, a purple-red coloring; when strong, almost brown precipitate.
Metallic zinc,.....	Precipitates metallic gold as a voluminous brown precipitate.
Potassa in excess,.....	No precipitate; after some time a green coloring and slight precipitate.
Ammonia,	Yellow precipitate—fulminating gold.
Carbonate of soda, or carbonate of potassa,	No precipitate in cold solutions, but when heated, voluminous precipitate like oxide of iron.
Bicarbonates of soda or potassa,	No precipitate.
Carbonate of ammonia,.....	Behaves like ammonia, carbonic acid being evolved.
Oxalic acid,	Dark, greenish-black precipitate, more quickly produced by heat.
Tartaric acid and soda,.....	Dark precipitate when boiled.
Sulphide of ammonium and Sulphide of hydrogen,.....	Dark brown or black precipitate.

These reactions are so characteristic that it is impossible to mistake gold for any other metal. At the same time, it may be stated that the protochloride of tin is the most infallible test, and is indeed quite conclusive. It has the advantage of being more delicate than the others—that is to say, it will indicate the presence of a smaller quantity of gold than any other reagent, not excepting the protosulphate of iron or the oxalic acid.

TESTS FOR METALS USUALLY ASSOCIATED WITH GOLD.—In examining an ore or alloy supposed to contain gold, it is often an object of great importance to determine the nature of the metals with which the gold is associated. These may be of high value on their own account, and, according to the quantities in which they are present, may greatly affect the value of the ore or mineral in question. To enter fully into this subject in connection with the rarer metals that are found associated with gold, would be of little practical use. The Editor will therefore confine his attention to the means of detecting and distinguishing those of most common occurrence—copper, silver, and platinum.

1. *Copper.*—It has been shown that copper is almost always associated with gold even in quartz, and that copper pyrites is one of those substances frequently mistaken for gold. When dissolved in acids, however, it gives characteristic actions, which render its presence easily distinguishable. One of the readiest tests is to introduce into the solution a piece of clean iron, when, if copper be present, it will be deposited on the iron in the metallic state. This experiment, remarks Dr. LYON PLAYFAIR, apparently showing the conversion of iron into copper, deceived the alchemists in their researches, and gave much support to the idea that one metal may be transmuted into another. The action depends, however, upon a simple exchange, the iron going into the solution in proportion as the copper goes out. Again, when ammonia is added in excess to a solution in which copper exists, it communicates to the liquid a rich deep-blue color. Ferrocyanide of potassium produces, with copper, a brownish-red precipitate, even when the metal is present in very small quantity. Carbonate of soda precipitates copper from its hot solutions in the form of an apple-green compound, which is a carbonate of copper, known, when artificially formed, as *verditer*, and when it occurs native, as *malachite*. Copper ore in the latter form exists abundantly in Australia—not, indeed, mixed with the gold, but constituting valuable mines, from which the ore is sent over to this country, with great profit, to be smelted in South Wales.

2. *Silver.*—It has been shown that gold appears to be invariably alloyed with this metal, sometimes to a very large amount. In its separate state it is readily distinguished, not only by its white color, but also by its specific gravity, which is only 10·4, or about one-half that of gold. It may be useful to state, that when in a very fine state of division, it is of a dark-grey color. It may be easily recognized by its chemical behavior to reagents, in which respect it differs from gold by its solubility in nitric acid at all temperatures, and in boiling or heated sulphuric acid. On the contrary, with hydrochloric acid, it forms a white curdy precipitate, which is the chloride of silver. If the nitric acid employed to dissolve it contain the least hydrochloric acid, the solution will become turbid by the formation of the chloride. Hence, when a mineral containing gold and silver is submitted to the action of aqua regia—nitro-hydrochloric acid—the appearance of this white precipitate will immediately indicate the presence of the latter metal. The chloride of silver is soluble in ammonia, and may thus be distinguished from many

other white precipitates; or it may be further tested by putting the precipitate into a crucible with carbonate of soda, and exposing the mixture to a strong red heat, when a button of pure silver will be obtained. By careful manipulation the amount of silver present may be accurately determined in this manner. If the mineral containing the silver be dissolved in oil of vitriol, it is readily detected by inserting a few fragments of copper, which causes the precipitation of the silver in a pulverulent state.

From the fact that silver, in greater or less proportion, is uniformly associated with gold in the native state, it may be useful to compare the following reactions with those given in the preceding page for the metal of higher value:—

TESTS FOR SILVER.	
Tests or Reagents.	Results.
Potassa,	Brown precipitate, becomes black on boiling.
Ammonia,	Brown precipitate, soluble in excess of ammonia.
Carbonate of soda or potassa,	White precipitate, soluble in ammonia.
Carbonate of ammonia,	White precipitate, soluble in excess of reagent.
Phosphate of soda,	Yellow precipitate, soluble in ammonia.
Oxalic acid,	In neutral solutions, white precipitate.
Sulphide of hydrogen and sulphide of ammonium,	Black precipitate.
Hydrochloric acid,	White curdy precipitate, soluble in ammonia.
Zinc or copper,	Precipitates white metallic silver.
Sulphate of iron,	In neutral solutions, white metallic silver.

3. *Platinum.*—This is another metal frequently associated with gold; and as it is one of the noble metals, and ranks in price between silver and gold, an ore which contains it in any considerable quantity is of great value. The specific gravity of platinum is about 21·5, and is, therefore, greater than that of gold. In short, platinum is the heaviest of all known substances. It is of a light steel-grey color, less ductile than gold or silver, but more tenacious, and will support greater weights on equal thicknesses of wire than any metal except iron or copper. It is distinguished from gold not only by its color, but also by its extreme difficulty of fusion; it does not melt by itself in the highest heat of a furnace, but softens sufficiently to admit of forging and welding, and in the arc of flame of the voltaic current, or before the oxyhydrogen blowpipe, it admits of being fused even in considerable masses. On the other hand, it resembles gold not only in its high specific gravity, as already stated, but also in the fact that it resists the action of all the simple acids, and is soluble only in aqua regia. This circumstance, together with its great infusibility, renders it importantly useful in many of the arts, and indispensable for various purposes in the chemical laboratory. It is the metal universally employed for apparatus which requires to be exposed to high temperature and powerful chemical agencies, without undergoing any change. It is, therefore, very desirable, as Dr. LYON PLAYFAIR has remarked, that those who go to the gold regions should look well for this precious metal, as it is likely to escape

the notice of the common observer from its less glittering appearance.

There are, however, certain chemical reactions by which platinum may be readily distinguished and separated from the gold in solution. Sulphate of iron and oxalic acid, which precipitate gold, do not precipitate platinum. When the latter is dissolved in aqua regia, and the acid neutralized by carbonate of soda, it is deposited as a black powder, if the mixture be boiled with tartaric acid and soda—the ingredients of a Seidlitz powder. Further, the addition of chloride of ammonium and alcohol to a strong solution of platinum, causes the deposition of a yellow crystalline precipitate, which is characteristic of this metal. These and other reactions may be summarily stated as follows:—

TESTS FOR PLATINUM.

Tests or Reagents.	Results.
Chloride of potassium or chloride of ammonium,	Yellow crystalline precipitate produced readily by the addition of alcohol.
Potassa or ammonia,	With chloride of platinum acts like the chlorides of potassium and ammonium.
Carbonates of potassa and ammonia,	In chloride solution yellow precipitate.
Carbonate of soda,	No precipitate.
Sulphate of iron,	No precipitate.
Oxalic acid,	No precipitate.
Protochloride of tin,	Dark-brown red coloring, no precipitate.
Sulphide of hydrogen and other sulphides,	Dark-brown nearly black precipitate.
Tartaric acid and soda,	On boiling, metallic platinum falls as a black powder.
Zinc,	Slowly precipitates metallic platinum as black powder.

Application of the Reagents.—Having thus described the properties and characteristic reactions of the different metals which it is desirable to look for as being frequently associated with gold, let it now be assumed that the substance to be examined is a piece of auriferous quartz. This must be first reduced to powder, and then boiled for some time in an earthenware or glass dish with aqua regia. The solution is then diluted with water, passed through a filter, and allowed to cool. If any silver be present, it will remain in the filter as a white precipitate, mixed with the quartz.

To the liquid which has passed through the filter, a solution of carbonate of soda is now added, until no more effervescence takes place. This will precipitate all the other metals which may be present except gold and platinum. These will remain in solution.

The liquid is again filtered, and a solution of oxalic acid is added until it ceases to produce effervescence, and has a sour taste; then boil; if there be any gold present, it will be precipitated as a black powder. The platinum, if any be present, will still remain in solution.

Decant or filter the liquid from the gold precipitate, and add to the former protochloride of tin, when a reddish-brown coloring will appear if platinum be present. Or, by boiling with tartaric acid and soda, the platinum will be thrown down as a black precipitate.

It has been stated that if any silver be present, it will be found on the first filter, mixed with the quartz. Wash this with ammonia, which, if copper be present, will produce a deep blue tinge. To the solution which comes through, add hydrochloric acid until the smell

disappears, and the silver will be thrown down as a white curdy precipitate.

It is evident that other methods and reagents may be adopted. For example, the original solution in aqua regia may be concentrated by evaporation, until it is very much reduced in quantity; then add about three-fourths of its bulk of spirit of wine, and, lastly, a saturated solution of chloride of ammonium. By these reagents the platinum will be thrown down as a yellow crystalline precipitate, while the solution filtered from this, and treated with sulphate of iron or boiled with oxalic acid, deposits gold.

By carefully weighing the gold obtained, the amount present in a given quantity of the ore or alloy may be exactly determined; but full details of the different methods of conducting the quantitative examination, including the assaying of gold ores and alloys by the dry process, will, to avoid repetition, be postponed to the close of the article.

GOLD-DIGGING TOOLS.—When the fact has been ascertained that a rock or soil really contains gold, and this in sufficient quantity to repay the labor of extracting it, the first operation is that of digging the soil or reducing the rock to fragments, with a view to its preparation for the subsequent processes. For the former of these purposes, the spade, the hammer, the pick-axe, and other common tools are employed; but for the special use of the gold-digger, who cannot conveniently carry a complete assortment of these, an ingenious combination of five tools, adapted for a single handle, has been contrived by Mr. T. LEE of Birmingham. Four of these are represented in the three annexed cuts.

Fig. 216.

Fig. 218.

Fig. 217.

Fig. 216 is a steel shovel, with loose handle fitted to it, to suit all the varieties. Fig. 217 is the same shovel, altered for use as a pick and scraper; this alteration is effected by withdrawing the prong of the pick from a

hollow socket made in the handle for its reception, and fitting the end of the handle into the eye shown in the shovel. Fig. 218 is the same handle fitted with an axe, formed with a pointed hammer, for granite-breaking. A fourth arrangement admits of forming the fifth tool, a powerful crow-bar, by fitting a short additional bar to the universal handle. Armed with this combination-tool, as the inventor terms it, the gold-digger is independent of the extensive array of ordinary implements; since, with the form of the apparatus represented in Fig. 217 on his shoulder, and the axe-head and short point of the crow-bar in his hand, he may journey freely to the scene of his operations; and when he commences work he is ably assisted by the peculiar fitness of the several combinations for the purposes of excavation. The incessant hard work of a pick rapidly wears away its point; but the combination-tool makes provision for one or more extra points to fit on the end of the pick. These are of small weight, and may be carried in the pocket. The pick, working in conjunction with the steel plate of the shovel, which is in the position of a scraper, to remove the loosened earth, effects a saving of time, while the quick change from one tool to another causes but little delay, in proportion to the convenience secured by the great portability of the arrangement.

MECHANICAL PREPARATION OF GOLD ORES.—Before subjecting the ore, or the auriferous gangue, to the chemical or metallurgical processes by which the gold is extracted, it has certain mechanical operations to undergo, the number and nature of which will be determined by the character of the ore itself, and its state of aggregation. The metal is rarely found in the shape of large nuggets, requiring only to be cast into ingots. It is generally either in the shape of dust, or spangles, or small grains intimately mixed with the quartz rock or the alluvial soil; and though far the greatest amount of gold is obtained by the direct washing of alluvial deposits, yet, as a considerable and perhaps increasing proportion is extracted from the solid rock, it seems to be the natural order to begin with those operations by which the rock is artificially reduced to the state of an auriferous sand or pulverized ore. These operations are *crushing*, *stamping*, and *grinding*, and are usually conducted by regularly-established mining companies, while individual diggers confine themselves to the washing of soils on which the same operations have already been performed by nature.

Crushing.—To reduce the fragments of ore, as obtained from the mine, to the proper size for their subsequent mechanical concentration, it is obvious that various arrangements may be employed, although in every instance the principles involved must be very nearly the same. For this purpose, the machine represented in Fig. 219 is frequently used, and consists of two large cylinders or crushing rollers, B, C, of cast-iron, moving in contrary directions in a strong iron framework, A A, secured to a solid wooden frame by means of screw-bolts. The bearings, D, E, of the rollers are so arranged as to slide in grooves, and consequently admit of the cylinders being either brought nearer to each other or separated to a greater distance. To admit of

the passage of large pieces of stone too hard to be broken, a certain elasticity is given to the machine by means of the lever, F G, which, by a sliding bar, and

Fig. 219.

the shoulder, K, constantly tends to keep the surfaces of the two grinding cylinders in contact, being loaded at its extremity with a heavy weight, H, which is adjusted to the hardness of the mineral to be broken.

After passing between the rollers, the crushed ores fall into the upper end of an inclined cylinder of coarse wire gauze, similar in construction and operation to that which is described in Vol. I., p. 169, in connection with the alum manufacture, and is there represented on the right hand side of Fig. 97. This cylinder receives an oscillatory motion from the same steam or water power which impels the rollers, and divides the pulverized ore into two classes; that which passes through the meshes of the gauze falls on the floor of the building, whilst those grains which are too large to pass through the sieve are carried out at its lower end, and fall into the buckets of an endless chain, by which this portion is again brought to the level of the hopper over the rollers for the purpose of being subjected to another crushing.

Stamping.—When the ore is required to be reduced to a finer state of division than can be readily effected by means of the crushing rollers, it is usually subjected to the pounding action of large wooden pestles, armed with iron heads, and moved either by steam or water power. The vertical wooden beams of which the pestles consist, are placed in a row, and are successively raised by cams fixed around a movable axle, so as to correspond with tongues attached to the pestles themselves. The cams are so arranged in three spirals that each pestle shall give three blows during each revolution, and as soon as the first in the series has been released from its cam, and begins to fall, the second cam of the same spiral comes in contact with the tongue of the next pestle; and so on until each has successively struck a blow, when the first pestle is again caught by the first cam belonging to the second spiral, and another series of rapid blows is given. The size of the iron stamp-heads varies according to the nature of the mineral to be broken; but their general weight is from three hundred to four hundred pounds.

In some of the more modern stamping-mills, both the axles and pestles are of iron; and a great improvement in the method of lifting the pestles has been recently effected by Mr. WALKER, of London, who substitutes a series of endless chains for the axle, and thereby increases the height of the fall of the pestles to any required extent. This arrangement is shown in Fig. 220, where A A A represent three of the pestles, while the top of the fourth is nearly on a level with the

collar through which they pass; and B denotes the endless chains revolving on the axles, C, D. When motion is given to the machine, the pestles are successively

Fig. 220.

raised through the whole distance from C to D, by projecting links on the chains, which are caught by tongues on the pestles, and these tongues are so arranged that each of them may in rotation be raised and released, as in the case of the spirals already described. A rapid succession of blows is thus struck; and each of the pestles when released falls on the mineral placed below with its whole weight, to which much additional force is given by the impetus acquired in descending through the space, D C.

In Mr. WALKER'S arrangement, as in the older stamping-mills, the minerals to be pounded are placed in a large wooden trough, in which are openings provided with sieves, or strainers, made by punching small holes in thin sheets of iron. The pulverized ore is carried through these sieves by a current of water admitted into the trough, which is then conducted over an inclined table, F, set in motion by the chain, E. The heavier and richer portions accumulate on this table, whilst the lighter are washed away into a series of reservoirs, in which they subside in the order of their specific gravity. The machine may be worked either by the hand or by steam or water power.

Grinding.—If it be deemed desirable to reduce the ore to a still greater degree of fineness, any form of apparatus, commonly used for grinding, may be employed. In Mexico the sands obtained from the stamping-mills are afterwards ground, with water, in a machine similar to the common mill-stone. Edge-stones, resembling the apparatus represented in Vol. I., Fig. 97, are also employed for the same purpose. It is necessary, however, that the grinding-mills be either of iron or granite. In the stamping-mill, the ore is already reduced to the state of sand; and, therefore,

the further pulverizing, if thought necessary, is usually associated with the operations of washing and amalgamating.

Washing.—It has been stated, that the greater portion of the gold is obtained from the alluvial soils or sands, on which nature has already performed the operation of crushing or pulverizing the rock. In general, therefore, the washing process is that with which the gold-digger commences; and this, indeed, together with the labor of extracting the soil from the pit, or from the bed of the stream or river, is the only operation usually resorted to for procuring the gold dust or nuggets which are sent from Australia and California. At the same time, the further process of amalgamation, when it can be conveniently employed, extracts the auriferous particles more thoroughly. These two processes—washing and amalgamation—which now remain to be described, are equally applicable to the pounded or pulverized rock, and to the auriferous soils which constitute at present the chief source of the supply of gold. The absolute necessity of washing the soil, to procure the precious grains, even when amalgamation is subsequently resorted to for more effectually extracting the metal and removing impurities, teaches the great importance of opening the pits or diggings in a situation where an ample supply of water can be obtained.

Hand-Washing.—The operation of hand-washing, which is the simplest method of separating the gold dust or grains from the soil, in a state of greater or less purity, has been already described. This method is extensively practised in South America, and the instrument employed is a round iron or zinc pan, Fig. 221, shallow at the sides, but sinking into a deep cavity in the middle, where the heavy particles of the gold accumulate, during repeated washings, which carry off the earth or stony matters. The gold is still mixed with impurities, from which it is ultimately separated by amalgamation.

Fig. 221

The Cradle.—Next in point of simplicity to the pan or basin, is the cradle, or rocking machine, which is much used in Australia and California, and is so named from its resemblance to the common article of domestic furniture. It consists, as shown in Fig. 222, of a wooden or tin trough, six or seven feet in length, under and across the bottom of which two curved bars of wood are fixed, to serve as rockers. Sometimes it is suspended by ropes from a cross-bar, supported at each end by two poles. The cradle, whether suspended or resting on the ground, is made to have a slight inclination from one end to the other, to allow the water to run off. At the upper end is placed a sieve, or coarse grating, on which the sand to be washed is charged; and the interior of the bottom of the vessel is provided with a few transverse bars, to arrest the heavier particles in their descent, while the water and lighter matters flow off. Four men are required to work this apparatus efficiently—one to dig and collect the auriferous sand, another to carry it to the cradle, and deposit it on the grating, a

third to rock the trough, and a fourth to attend to the supply of water, and the uniform washing of the material. The grating intercepts the stones and coarser

Fig. 222.

gravel; the earthy matters, containing the particles of gold, pass through; and the latter, with the heavy ferruginous sand, are arrested by the transverse bars, while the lighter portions are carried down by the water to the lower end, which is left open, or where a perforation is made to allow the current to escape.

After continuing the operation, with repeated charges of the auriferous sand, during a sufficient period, which will vary according to the richness of the material, the concentrated ore which has accumulated behind the bars of the cradle, is collected in a tin pan, shown in the same figure, and after being dried in the sun, the lighter impurities still remaining are removed, by blowing strongly on the mixture with a pair of bellows or otherwise.

Gold-Sifter.—A more refined apparatus, for washing and sifting the auriferous ore, which was registered by

Fig. 223.

Messrs. LAMBERT and DANBY of Liverpool, is represented in Fig. 223. It consists of an open frame, A A, carrying a receiver, B B, in which is a revolving barrel, set with a series of pins, D, working in gear with other

corresponding pins, which are made fast in the receiver. The pin-shaft, G, which carries a fly-wheel, H H, is driven by the winch F. The other end of the shaft works a crank, I, from which a connecting-rod, J, passes down to a pump, K, for supplying water through the pipe, M M, to the working-chamber. Beneath the latter is a box, containing three separate sieves, N, O, P, of graduated fineness, and made to oscillate by a lever arm at Q, acted on, through a rod, S, by an eccentric, R, on the shaft, G. At the foot of the frame is an incline, T, for running the water away into the reservoir—strips of wood being set across it, to arrest any small particles of gold which may escape through the last sieve. At U is a valve, beneath the receiver, B, for discharging the agitated mass upon the sieves.

This is a very complete and easily-worked machine. By the simple turning of the winch handle, not only is water supplied in abundance, either from a river or cistern, but the mass is well comminuted, intimately mixed with the water, and reduced to an impalpable slime by the action of the pins, D; so that when accumulated in sufficient quantity to force a passage through the valve, U, the great body of the mixture readily passes through the sieves, and flows away into the reservoir, leaving only the grains of gold and other hard substances which cannot penetrate the meshes, while the finer particles of the precious metal, or what may be termed the gold dust, collect by their superior gravity behind the transverse bars of the incline, T. The series of graduated sieves is important for assorting the particles of gold, and the stony or earthy matters with which they are mixed, into grains of different sizes—the product or contents collected in each sieve being nearly uniform. This greatly facilitates the ultimate washing; for when the grains of an auriferous mixture are of different sizes, the smaller surface of one fragment, in proportion to its weight, compensates in some measure for the greater density of another grain, and thus causes it to assume a position in the series of deposited layers, to which, by its constitution, it is not entitled. This difficulty is found to constantly occur in practice; and it is with the view of obviating it as much as possible that care is taken, in the best machines, to separate, by means of sieves, into distinct parcels, the fragments which have nearly the same size.

Methods of Washing in Brazil.—In Brazil, the excavations and river-washings are entirely conducted by negroes, who are furnished with a large wooden bowl, about two feet in diameter, and nearly one foot in depth; as also with a leathern bag, which is tied before them, for the reception of the particles of gold dust collected, after repeated washings, in the bottom of the bowl. Sometimes, however, the final washing of the auriferous sands is conducted in long shallow troughs, the bottoms of which are covered with coarse baize, or with skins tanned with the hair on, and placed with the grain against the current of water. The baize, or skin, is at short intervals removed from its frame, and beaten over a shallow tank, containing water; it is then carefully washed in the same vessel, until every particle of the gold is removed, after which it is replaced in the trough for receiving the auriferous sands, already partially washed. To obviate the inconvenience of so frequently

removing the skin or cloth from the vessel in which the washing is conducted, an endless web of the same material has lately been introduced, which is made to move by means of rollers impelled by the water-wheel employed for stamping the ore. The motion communicated in this manner is opposite to that of the stream of water flowing over the table; and while the upper portion moves upon this table, extended between the two rollers, collecting, in its progress against the stream, the particles of gold, the lower or returning portion hangs down loosely, and is drawn through a vessel of water, in which the gold is washed off and collected.

Methods of washing in Hungary and the Ural.—In Hungary and the Ural the methods of washing are various, but the principle generally adopted is that of inclined troughs or tables, traversed by transverse grooves—a principle adopted in the cradle, and almost all other washing-machines. On the large scale, however, these inclined tables may be compared to the apparatus for washing coal, represented in Fig. 74, at page 95 of this volume. The sand to be washed is placed in the

first groove of the series, and is there exposed to a current of water, until the gold, mixed with a portion of ferruginous sand, alone remains in the furrows. The concentrated ore is then removed into flat wooden basins, in which the impurities are gradually separated by repeated washings, or these may be removed at once by amalgamation.

Among the different methods adopted in the Ural districts, there is one by AGTÉ, in use at Alexandrowsk, which is precisely similar in principle to that above described, though somewhat more complex in the arrangements. These are represented in the annexed engraving—Fig. 224—where B is a conical cylinder of sheet-iron, about eight feet in length, and having a mean diameter of about three feet six inches. This cylinder is pierced with holes of about half an inch in diameter, and is fixed on a spindle communicating by a train of wheels and shafts, with a water-wheel, horse gin, or any other prime mover, from which it is capable of receiving a rapid rotatory motion, so as to make from thirty to forty revolutions in a minute. A crank on

Fig. 224.

the shaft which communicates motion to the cylinder, works the double pump, C, at the back of the frame, which raises water from a well or some other convenient reservoir to the cistern, D, and from this it is conducted by pipes into each end of the cylinder, B. The ends of the cylinder are open, and the pipes are so arranged as to diffuse the water pretty equally over its interior surface. Nearly on a level with the top of the arrangement is a line of rails, on which the auriferous sands are brought in wagons to the hopper, E, from which they fall into the smaller end of the revolving cylinder. The latter by its centrifugal action ejects through its numerous perforations the water and finer particles of sand and gravel, which are received upon the inclined platform below, whilst the larger fragments are carried down to the under end of the cylinder, and there fall into a box which does not appear in the engraving. Any gold nuggets which may be mixed with these fragments, being well washed and burnished in their

gradual progress through the cylinder, are now readily perceived and picked out. The platform, which receives the water and auriferous sand expelled through the holes in the cylinder, is provided like the cradle, the sifter, and the arrangement last mentioned, with numerous cross bars, for the purpose of checking the current, and arresting the heavier particles of the ore; and after traversing this platform, the current descends to a concave table or tye, G, which is also furnished with a series of wooden bars, at intervals of two or three feet. The sands which have arrived at this part of the machine are kept constantly stirred or agitated by square frames carrying blunt iron knives, and suspended, pendulum-wise, by vertical bars, H H, from a wooden axis above the tye, turning on gudgeons, and placed in the direction of its length. The frames are made to fit into the cavity of the tye, and a swinging alternating motion is given them by means of the rods, L L. In this way the sands are well stirred; and while the heavier or

richer portions are retained and accumulated behind the check-boards, the lighter materials are carried away with the current at the lower end, &c, of the tye or buddle, from which, if not sufficiently impoverished, they are received on a fresh series of tables, furnished with similar agitating apparatus, and are finally allowed to pass off. This machine is able to operate on two hundred tons of alluvial sand in the course of an ordinary working day of ten hours, with the labor of twenty men and six boys, including ten men for removing the waste, if in a level country, without advantages for otherwise clearing it away.

The partitions in the bottom of the tyes are ribs of two inches high and two and a half inches wide, held by screw-bolts and nuts, and are removed every now and then for the washing out of the concentrated auriferous sand. This is done the more frequently in proportion as the sands are richer in gold.

Fine Washing.—The gold obtained from all the preceding operations, is still so much mixed with sand and other substances, as magnetic iron, pyrites, *et cetera*, that it requires to be further concentrated, either by additional washing or by amalgamation. The powder collected in the buddles or tyes is commonly of a grey color, and is termed *grey schlich*. By the cylindrical machine above described, the original ore or auriferous sand is concentrated to about three tons of schlich for every two hundred tons of the crude material employed. For its further cleaning and concentration by washing, it is treated on uncovered tables or frames, seven to ten feet long, by three or four broad, and divided into an upper and lower part by a lath nailed across the bottom. Also, across the upper part, are fixed two boards, which regulate and equalize the flow of water. The schlich to be washed is placed upon the upper division, and the workman, standing upon the frame in wooden shoes, mixes the sand with the water, and gently moves it against the current, towards the head of the arrangement, with a small wooden hoe or heath-broom. The gold thus arranges itself chiefly near the head-board, and when a certain amount is collected, he rakes it with his hoe or broom, just strongly enough to draw down the earthy particles over the lath to the lower division, without disturbing the heavier and richer deposit. This delicate operation requires skill and dexterity, and must be continued till all the coarse fragments are removed, after which the flow of water is reduced. The workman, by light brushing, raises again all the slime which may still remain, and as much as possible of the magnetic iron ore, and takes up as the product of his manipulation the *black schlich* which is left. The upper department of the box being thus cleared, he now brings upward that which has settled in the lower part, and passes it once, twice, or thrice, through the same operations. This process, for which the most skilful and experienced workmen are required, is termed *fine washing*. The black schlich or ore thus concentrated is dried, and is freed from a further quantity of magnetic iron, by the use of an artificial magnet or a piece of loadstone.

The *gold troughs* used in Hungary and Transylvania for the final washing of the powder or schlich obtained from the cloth-covered tables already alluded to, as well

as the process of washing, are similar to those just described. In these countries a broom of heather or birch is generally used instead of the hoe; and in Transylvania the troughs, which are of larger dimensions, are fitted with two traps in their channels, into which the different qualities of schlich are swept at different stages of the process. Even after this fine washing, the resulting products are sometimes further concentrated in the bowl or washing-pan, and so reduced to a state fit for melting, or they are subjected to the process of amalgamation.

AMALGAMATION OF GOLD ORES.—The greater part of the gold of commerce is imported in the shape of dust, or small grains, extracted from the auriferous soil by the simple washings above described, and brought, by a frequent repetition of that process, to a state of sufficient purity to be immediately melted into ingots, more or less mixed with silver or copper. Sometimes, however, instead of the tedious process required to bring the gold by mere washing to that degree of concentration which is necessary for its subsequent fusion, the purification of the gold by this method is only carried to a certain point, and the operation is concluded by amalgamation, or, in other words, by mixing the partially-concentrated ore with mercury, which seizes on the particles of gold, and thus completely separates and extracts the precious metal from the soil or gangue in which it is found.

It may be laid down as a general rule that amalgamation would be advantageously resorted to in all cases, as the finishing process in those operations which precede the metallurgical treatment of gold. By no other method can the precious metal be thoroughly extracted from the gangue, and so effective is its action, as compared with mere washing, that it has often been applied with success to extract a remunerative return from the refuse or waste sands which have passed through the gold-digger's cradle. Its profitable application, however, will depend on the nature and richness of the auriferous soil. If the gold is abundant, and is found in considerable grains, as in many parts of the recently-discovered gold regions, the greater and most valuable part of it is readily separated, and easily concentrated sufficiently by mere washing. On the other hand, if, as often happens, the gold is diffused through a dense and heavy gangue, in particles so minute as to be invisible to the unassisted eye, it is evident that these particles will float away with the current when the sand or crushed ore is washed on inclined tables, and that their extreme minuteness will counteract the effect of that difference in specific gravity by which it is so easy to separate the larger grains when diffused through a less dense soil. On the whole, therefore, while amalgamation must be applied in all cases where it is desired to extract, practically, the whole of the gold, it is more especially applicable to its extraction from quartz rock, from heavy pyritous ores, and from other descriptions of gangue, through which it is diffused in a state of extreme division. And as the mercury exerts no chemical action, but may be again separated from the gold with little loss, the advantages afforded by the great efficiency of this process are not materially restricted by economical considerations.

From the nature of the ore which is usually treated by amalgamation, this operation is generally associated with the preliminary processes of stamping or grinding, as well as partial washing. One of the simplest and most primitive methods adopted is described by Mr. W. B. ADAMS as having been witnessed by himself, in the course of a week's trip which he made with a South American *cateador* or gold-mine hunter, for the purpose of acquiring information. When the travellers had passed the extreme limit of vegetation, and entered a narrow ravine between lofty ridges of hills, the *cateador* began to examine carefully the stones at his feet, which became more and more abundant, till nothing was seen but clay-slate shingle. On the second day, after turning up another ravine, he picked up a stone, which he examined with some attention, and then went on. About mid-day the travellers stopped, and the gold-hunter picked up a fragment of quartz from amidst a great variety of stones. He then placed it on a flat piece of rock and pounded it, and ground it to powder, which he placed in a horn, and poured some water on it, shaking it about with a peculiar motion. A second and a third water were added, and finally he showed a fringe of fine gold on the black horn, along the edge of the quartz sand. No vestige of gold could be observed in the quartz before grinding. Satisfied with the result, he went on tracking the fragments of quartz, till at last the travellers came to the vein, in granite rock. He selected a few pieces, which he put in his wallet, then piled up some stones to mark the spot, and they set out on their return home. In a neighboring valley, he exhibited his stones to a proprietor, whose business it was to extract gold from quartz, and sold him his discovery for the sum of twenty-five dollars.

The mode of extracting the gold was very simple, and is thus described. A vertical running-stone traversed in a circular stone trough. Quartz, broken to the size of walnuts, was thrown into the trough, with several pounds of mercury. A small stream of water trickled into the trough, and flowed over at a particular spot, carrying with it the finer ground particles. At the depth of a foot it fell into a goatskin bag, with some quicksilver in it; thence into a second, third, fourth, and fifth bag, as long as any fall could be obtained. After working several hours, the mill was stopped, and all the mercury collected in a long narrow linen bag. Into this it was forced with a stick, and then the bag was squeezed till all the uncombined mercury passed through, and only the amalgam of gold was left. This was placed on a piece of strongly-heated iron, resting on a brick standing in water. An earthen cupola was laid over the whole, forming a water-joint at bottom, and the neck of the cupola descended into water. Thus the fumes of the mercury, sublimed by the hot iron, were condensed and collected in the water, and the metal saved. The spongy gold, called *pine-gold*, was left on the iron plate.

In Piedmont, where veins of auriferous pyrites have been worked from a very remote antiquity, the extraction of the gold is effected almost entirely by amalgamation. The produce is very variable in different

localities, but averages about twenty shillings in value from 150 pounds avoirdupois of the auriferous ore. The amalgamating mills are erected in great numbers on the banks of the various rivulets which traverse the mountains. These establishments usually consist of small wooden buildings, each of which contains four amalgamating machines. They are erected at intervals over the whole length of the valley of Anzasca, from Chamnaga to Pie di Mulera; and in this valley there are more than two hundred mills procuring a remunerative return from a very poor soil, by the process of amalgamation.

The ore or mineral, when extracted from the mine, is first subjected to a grinding or triturating process in a machine resembling in its action and operation the common millstone, and driven by a water-wheel. When thus reduced to powder, it is carried off by a stream of water to the amalgamating mills, represented in Fig. 225. Whilst held in suspension in the water, it is conducted first to the upper mill by the spout A, from

this to the second by the spout B, and so on in succession through the whole series. Each mill consists of a cast-iron basin, D E G F, fastened by screws to the top of a strong frame or table, and fitted in its centre with a tubulature, traversed by the axis H H', moved by the toothed wheel I I', and with which revolves a wooden muller, K K, fixed to the upright spindle by the iron collar M M'. This movable part of the mill has externally the same form as the internal cavity of the fixed iron casting, G, in which it revolves horizontally, at the distance of about half an inch from its surface; at the same time it is furnished with several iron ribs, which come nearly in contact with the interior of the casting. The rotating muller is made of hard wood, and is hollowed out like a funnel, in which the auriferous slime accumulates, and gradually penetrates into the interval between its external surface and the bottom or interior surface of the iron basin, from which it flows to the next mill by the spout B or C.

In the bottom of the fixed vessel is put about half a hundredweight of mercury, which lies to the depth of about half-an-inch, and when the machine is set in motion, the pounded mineral is constantly agitated and mixed with this fluid metal by means of the iron ribs nailed to the bottom of the muller. The minute particles of gold are thus immediately dissolved and taken up by the mercury, while those which escape combination in the first mill are arrested and retained by the second, third, or fourth of the series.

After working the mills continuously for several weeks, the time required being longer or shorter according to the richness of the mineral under operation, and when the mercury is judged by the workmen to be sufficiently charged with the precious metal, the mills are stopped, and the amalgamated mass is taken out. It is important not to protract the process unnecessarily, otherwise a serious loss of mercury is sustained, occasioned, perhaps, by its partial conversion into a sulphide, which is carried away with the current. The mercury, when drawn off, is washed, and then strained or filtered through a piece of chamois skin, for the purpose of obtaining the solid amalgam, which usually contains about one-third of its weight of pure gold. This is separated from the combined quicksilver by distillation in an iron retort, the beak of which dips into a vessel containing water. The whole of the mercury in actual combination with the gold is thus recovered, and the only loss sustained is that which has been carried away by the current in the shape of sulphide and otherwise. DUMAS states that the loss incurred in this manner is equal to about one-fourth of the quantity employed; but so large a waste must result from careless manipulation.

In the Salzburg Alps, the gold ore is worked in lodes or veins, and the precious metal is separated by three processes—washing, roasting, and amalgamation. It is chiefly in actual *mining*, not in what is popularly known as *digging*, that the latter two operations are brought into requisition. The mineral extracted from the lodes, in the locality above-mentioned, is divided into two classes or qualities—first, that which is so poor in the precious metal that the grains or particles are not visible; and, second, that in which the golden grains may be detected. Both are crushed or stamped; but in treating the former this operation is preceded by roasting, to facilitate its pulverization under the action of the stamps. This roasting, though not practised at all the mining establishments, is useful, not only for the purpose above-mentioned, but also for converting the sulphides and arsenides into fine light oxides.

The mineral, whether roasted or not, having been passed under the stamps and well ground, is washed first on movable inclined tables, and then in wooden hand-bowls. The gold is thus obtained in a state of considerable concentration, and then the work is completed by amalgamation. In the Salzburg country this last operation is conducted in a peculiar manner, and requires a machine constructed with much care, somewhat resembling in its principal parts the common flour mill. The upper mill-stone revolves horizontally in a hollow cylinder, and over it is placed a hopper, which can be depressed or elevated at pleasure. The object of this hopper is to spread over the mill-stone a uniform layer of mineral. Below are placed three iron cylinders, in which the amalgamating mills revolve, with their axes resting on bearings which admit of being raised or depressed according to the nature of the mineral under treatment. Water is admitted by a stopcock into the upper mill, where it is intimately mixed with the mineral into a slime or paste, and from this it descends to the amalgamating mills by an inclined plane terminating in three pipes or gutters, which

divide it equally between the three cylinders. From these the fluid amalgam is conducted by a second inclined plane to a washing apparatus.

The process begins with pounding and washing. The mineral, thus pulverized and partially concentrated, is then mixed with a certain quantity of chloride of sodium and thrown into the hopper, from which it descends over the inclined plane into the hollow cylinder containing the large mill-stone. When the hopper is emptied of the first charge, more mineral is poured in till the upper cylinder is full, and then water is admitted, which carries the auriferous slime, so formed, over the second inclined plane into the three amalgamating mills below. Before introducing the quicksilver into the cylinders containing these mills, the machine is allowed to work on the mineral for the space of two hours; the mercury is then added, in quantities of about fifteen to eighteen pounds at a time. The quantity of mercury, water, and mineral introduced should be in the proportion of fifty, thirty, and one hundred; or, in other words, *for every hundred pounds by weight of the mineral, there ought to be fifty pounds of quicksilver, and thirty of water.* In some establishments, a quantity of mercury equal in weight to that of the mineral is introduced, and the work proceeds with all the greater certainty, although the waste or loss of mercury sustained may in this case be more considerable.

In this operation the amount of water introduced is not a matter of indifference. If it be too small, the mixture will be pasty, the motion of the mill will be obstructed, and the ore will adhere to the sides of the cylinders, without undergoing amalgamation. If, on the contrary, the mixture be rendered too fluid, the particles of gold and silver, which are generally found together, will be carried away too rapidly, and in this case also will escape combination with the mercury.

On the other hand, it is evident that an adequate supply of the fluid metal is a point of the greatest importance, as it acts on the gold only in proportion to the extent of surface which it exposes to the mineral. To enlarge this surface, the vessels in which the amalgamation is conducted have latterly been formed like an inverted cone, terminating in a hollow sphere. It is with the same object in view that a rotatory motion is given to the mass; for the centrifugal force thus communicated raises the mercury against the sides of the cylinder or cone, which widens or expands upward so as to increase the extent of surface exposed, and then the mercury falls back again into the mass by its own weight.

Although the numbers given above may convey a general idea of the proportions of the three ingredients to be employed, it deserves to be remarked, that these must be varied according to the nature of the mineral under treatment, and that indeed the quantity of mercury should be proportioned rather to the bulk or volume of the ore than to its weight. The lighter the ore, the more space will it occupy in the cylinders; and as the mercury should rise over the mass, more of it will be required in this case to insure its union with the gold or silver present. If the mercury be in small quantity, the amalgam is not sufficiently fluid, and is partially converted into a dust or

frothy substance, which flows away with the water when the latter is allowed to escape from time to time, so that a considerable loss is sustained both in gold and quicksilver. If, on the contrary, the quicksilver be present in excess, the gold combines with it more rapidly and more thoroughly; the amalgam remains fluid, and readily separates from the other materials with which it is mixed. It is therefore by no means economical to stint the supply of mercury.

There are some indications by which a judgment may be formed as to whether the mill is operating in a satisfactory manner. If particles of gold, not amalgamated with the mercury, are observed in the cylinders, this is a proof that the millstone is too high, and does not come into close enough contact with the mineral, in which case the mercury, not being agitated, remains inactive at the bottom of the vessel on account of its superior gravity. If, on the contrary, a quantity of quicksilver-dust and frothy amalgam be observed on the cylinders, this is an evident sign that the former has ceased to absorb the gold, and that more must be added.

It usually requires about sixteen or eighteen hours to complete the amalgamation. The final washing is then proceeded with, and is effected by a current of water, which carries away the earth, and purifies the amalgam from those substances not combined with the mercury. This operation is performed in a wooden vessel of a conical form, the bottom of which slopes to the centre, and is fitted with a stopcock. A circular movement is given to this vessel, that the mass may be kept in a state of agitation, and the lighter parts carried away by the current of water admitted, while the amalgam falls by its own weight to the bottom of the vessel. This operation is repeated several times.

When the washing is concluded, the next and last step in this process is the separation of the mercury. With this view the liquid amalgam is put into a chamois-skin or woollen bag, and well squeezed. The mercury which passes through the skin or cloth, still retaining a small quantity of gold, is carried back to the cylinders to be employed in amalgamating the next charge. There remains in the bag a semi-solid amalgam of gold, which is put aside for distillation. By wetting the bag which is to be used for straining, a larger amount of amalgam remains, and the mercury which passes through carries with it less gold. When the solid amalgam is very pure, it is rather white in color; but when alloyed with lead or copper it is less so, and does not produce the same crackling noise when crushed or broken. The amalgam, as in the other cases already mentioned, is deprived of its mercury by distillation; or, if a small portion of that metal still remains, it is expelled in the subsequent fusions to which the gold is subjected with a view to its final purification.

The preceding process, which is practised, as already stated, in the Salzburg Alps, presents some peculiarities. The amalgamating mills are somewhat similar to those employed in the Tyrol, but these mills are fed in a different way, and a larger proportion of mercury is used. The last circumstance is highly advantageous, and ought to be imitated in all cases where the nature

of the gangue, or mineral under treatment, will admit of it; for, with an ample supply of quicksilver, the extraction of the gold is not only more rapid, but more complete. But, with a strongly pyritous gangue, like that of most of the Piedmontese mines, the employment of a large excess of mercury would seem to be productive of a heavy loss of that metal arising from its conversion into a sulphide.

For effecting the amalgamation of the concentrated auriferous ore or black schlich *by manual labor*, the machine represented in Fig. 226 is sometimes employed.

This consists of a species of churn, *v*, made of sheet-iron, through the lid of which passes a spindle, *x*, of the same metal, carrying a kind of paddle-wheel, *A*, which is turned by the winch-handle, *w*. The bottom of this machine is first covered to a small depth with mercury, and then the concentrated ore is added by an opening at the top in successive small portions, while, at the same time, the whole mass is continually agitated by stirring; and this process is continued till the mercury is judged to be sufficiently saturated with the gold. The amalgam is then taken out and treated in the usual manner, by washing, straining, and distillation.

Fig. 226.

It may be stated that the same apparatus is highly convenient for the original washing or concentration of the ore, or auriferous sand, and, when employed for that purpose, is familiarly known as the *dolly-tub*. In this case it is nearly filled with water; and whilst one man keeps the agitator in constant motion, another throws into it, in small portions at a time, the auriferous earth. When the full charge has been thus introduced, the cross-bar, *B C*, through which the spindle works, is removed, and the agitator is quickly taken out. The materials held in suspension are then allowed to settle according to their respective gravities, and, consequently, the gold, together with all the heavier particles, will sink to the bottom. When these have subsided, the water is drawn off by the stopcock, *s*; the upper portions of the deposit are cautiously removed and thrown away, while the heavier portions at the bottom are collected for further concentration, either by the hand-bowl or otherwise. But although the *dolly-tub* may thus be applied to the double use of a washing and amalgamating machine, it is less convenient for the former purpose than the cradle, and other kinds of washing apparatus already mentioned.

Another machine, which is easily worked by the hand, was contrived by Mr. BERDAN of New York, in the heat of the Californian mania, and is known as BERDAN'S Gold Ore Pulverizer and Amalgamator. In this machine, the pulverizing process is effected in a large hemispherical iron vessel, rotating on an inclined spindle, and having within it a weighty iron sphere, connected by a pivot and bearings set in an inclined

position loose upon the central spindle of the basin, in such a manner that its gravity causes it constantly to maintain the lowest possible position in the basin, whilst its axis of rotation, owing to the pivot connection, is inclined to that of the basin. The motion thus communicated to the sphere is not a mere rolling, but a species of spiral action, which is said to be very effective in reducing the ore. The basin is made to revolve by suitable gearing, a ring of teeth being cast or fitted on the outside of it for this purpose, and its revolution communicates motion to the sphere. A quantity of mercury is placed in the bottom of the basin, and the ore is reduced to powder entirely beneath its surface, being latterly washed away by a current of water which runs into and out of the basin, and is kept in a constant state of agitation by the motion of the vessel. As heat considerably strengthens the affinity of the mercury for the gold, a new and important feature was introduced into this machine by the employment of

a furnace in connection with the apparatus. This furnace or fire-place is of a conical shape, and rests by its lower smaller end on a collar upon the basin-spindle, just above the step. It was stated, though probably with much exaggeration, that while the machines previously employed extracted only from thirty to forty per cent. of the gold in a given quantity of quartz, the most searching chemical analysis was unable to detect any gold remaining in the *tailings* or waste matter from Mr. BERDAN'S machines, and that these, moreover, were very profitably employed in re-working the tailings from other machines. It does seem probable that the introduction of a furnace to heat the mercury might greatly increase the efficiency of this apparatus, and that the same improvement might be applied with good effect in other machines. At the same time, it is obvious that if caution is not exercised to prevent the heating of the mercury beyond a certain point, a very great loss must be sustained by its volatilization.

SMITH'S Portable Gold Amalgamator, which is represented in perspective in Fig. 227, also admits of being worked by the hand, and is designed for the use of emigrants, and the proprietors of mines and estates where gold may be supposed to exist. This machine is divided into three compartments. In the first, A, are arranged a set of powerful crushers, and a series of agitating plates, intended for stiff and hard clays; two or three revolutions reduce the matter to a floating pulp, which flows off through a pipe, DD, leading from this part of the machine to the amalgamator, C. The pipe is provided on its lower side with a series of boxes or valves, which can be opened or shut at pleasure, and only that portion of gold passes on to the amalgamator which cannot be detained in these valves. The second compartment, B, is constructed for the reception of the looser earth, and consists of a drum or barrel in which revolves an agitating apparatus. Nothing is allowed to leave this until it is perfectly worked, when the opening in the side of the barrel is turned downward, and all stones and other foreign matters are dis-

charged into the chamber beneath, in readiness for receiving a fresh supply of the auriferous earth. The chamber into which the contents of the barrel are thus discharged is relieved from time to time by raising a sluice; and the floating matter then passes over a long

Fig. 227.

trough, H, provided with check-bars, to empty itself into the amalgamator—all solid particles being, in this case also, arrested in their passage from the washer, while, by a simple arrangement which it is unnecessary to detail, the action of the machine keeps up a constant supply of water. The third portion, C, of the machine, or that compartment which is properly the amalgamator, is so constructed as to expose a large surface of mercury to the action of the floating matter, and by means of washers and balls made of wood, to render it impossible for any portion to escape coming into contact with the mercury. This part of the apparatus admits of being locked up, so that none of the gold can be abstracted without the knowledge of the party possessing the key. The machine requires only two men to work it; but it may also be driven by steam or water, and gives, when properly constructed and managed, very satisfactory results.

DISTILLATION OF THE MERCURY.—When the amalgam has been formed by any of the methods or machines above-described—in all of which the object kept in view is to place the particles of gold in the most favorable condition for coming into contact with the mercury, and combining with it—and when the fluid metallic mass has been washed, and the excess of uncombined mercury strained off, the last operation required in this method of treatment is the separation of the mercury which remains combined with the gold in the form of a semi-solid amalgam. This is performed by distillation at a high temperature, in a cast-iron vessel prepared expressly for that purpose. Different forms may be given to the apparatus, according to the scale on which the operation is conducted; but a very convenient one is that represented in Fig. 228, where A, is a cast-iron sphere or shell made in two parts, and capable of being joined together in the middle by a flange and screws. From the top of the upper hemisphere proceeds a bent iron pipe, D, which dips into water contained in the vessel, C—the whole forming a convenient iron retort. When used, the hemispheres are taken asunder; the amalgam is intro-

duced, and the two halves are again screwed together and well luted with some refractory substance. The retort is then placed on any convenient support over the fire, B, which may be of wood or coal; the heat is

Fig. 228.

gradually raised, and the sublimed mercury, which is conveyed away by the tube, D, is condensed and collected in C. Care must be taken to prevent the end of the pipe from dipping too deeply into the water; for if the temperature of the fire happens to fall, a vacuum is produced in the retort, which, if the pipe be too deep, will cause the water to rush up into the globe, and produce an explosion. The end of the pipe is therefore introduced just below the surface of the water, so that if a small portion of the water be drawn up into the pipe, that which remains in the condenser, C, immediately sinks beneath the level of the orifice, and all danger is averted.

When the distillation is concluded, which is known by the cessation of any further accumulation of quicksilver in the condenser, this distilled mercury is collected to be used for future amalgamations. The gold which remains in the retort, A, is now comparatively pure; but still contains a mixture of silver, copper, or other metals, in greater or less proportion, according to the sources or localities from which it has been procured. The separation of these, with a view to the obtaining of the gold in a state of absolute purity, will form the subject of the next department of this treatise.

In the meantime, it may be repeated that the amalgamating process is chiefly applied in the working of auriferous veins, or *gold-mining* properly so called, in contradistinction to the much more common method of extracting the gold from drift-beds or stream-mines, by the mere operation of washing. In the former case, the gold, generally in very minute particles, is mingled with various other minerals and rocks, as pyrites, zinc-blende, quartz, *et cetera*, and can only be extracted after the whole has been reduced by stamping, to a very small size—in which state, the gold, often so minute as to be invisible, would be almost entirely carried away by a stream of water. It is here therefore that amalgamation offers peculiar advantages, as the mercury seizes on the gold, however finely reduced, and none of the precious metal is lost—provided the precaution be taken not to pulverize or stamp the ore too fine, when about to be submitted to those preliminary washings which precede the amalgamation. On the contrary, when about to be brought into actual

contact with the mercury, the ore or schlich cannot be reduced too small; and hence the importance of actually pounding it, if possible, under the surface of the mercury.

From these considerations it will be readily seen that the process of amalgamation is not only applied with advantage in the working of auriferous veins or lodes, but that it may also be employed to procure a profitable return from the re-working of the tailings or refuse of the Australian or Californian gold-diggers. The Editor has little doubt that the greater part of the abandoned diggings, which have yielded a large return by mere washing, will, in course of time, be worked over again by amalgamation; and, indeed, this *gleaning process*, as it may be termed, has already been applied in many cases with highly satisfactory results. To give an idea of what may be done with poor ores, when system and skill are brought to bear, it may be sufficient to state the average produce obtained from the stamped ores at Schemnitz, in Hungary, in 1842—recollecting that these had to be broken from the solid lodes at depths extending to two hundred fathoms. The total quantity stamped in that year was above forty thousand tons, and the average of the useful metals extracted from fifty tons was: gold, three ounces; auriferous silver, derived from the separating processes, by buddles or tyes, *et cetera*, three pounds three-quarters; lead, similarly obtained, eight hundredweight one-third; the ratio of the gold to the other materials being in this case as one part to half a million. In the case of a particular mine, called Siglisberg, not producing lead with the stamped ores, the ratio of gold was only as one part to seven hundred and sixty thousand; of auriferous silver, one to twenty-four thousand. Now, it is interesting and instructive to compare with this economical extraction of minute quantities from poor ores by the process of amalgamation the produce of the manipulation by washing at the Siberian workings, where a common average of the sands worked to profit is half an ounce in one hundred hundredweight, or fully double the amount last mentioned, and yet even the poorer ores of Hungary yield a remunerative return by amalgamation. It follows, that by the same process many auriferous sands in Siberia, as well as in other countries, which are at present neglected, as being too poor for washing, might be advantageously worked.

Separation of Gold from Arsenical Pyrites.—Another illustration of the importance of scientific knowledge in the working of gold mines, is furnished by the recent application of PLATTNER's method for the separation of gold from arsenical pyrites, in consequence of which the mines of Reichenstein, in Silesia, which, as already stated, had been abandoned for more than five centuries, were reopened with advantage eight or ten years ago. This successful application of a purely scientific suggestion is due to the skill and enterprise of W. GUETTLER, of Reichenstein, to whom, in conjunction with Professor PLATTNER, the inventor, a council medal was awarded at the Great Exhibition of 1851, for a series of specimens illustrating the different stages of the process. The principal agents employed are chlorine and sulphide of hydrogen. The following account of this novel and ingenious process is given in the published re-

ports of the Jurors :—The ore at Reichenstein is an arsenical pyrites, containing about two hundred grains of gold in the ton. The ore is roasted in a reverberatory furnace, surmounted by a large condensing chamber, in which the arsenious acid is condensed as fast as it is volatilized. There then remains, on the floor of the furnace, oxide of iron mixed with a certain quantity of arsenic, together with the whole of the gold. This is placed in a vessel so arranged that a current of chlorine can be passed through it, by which the gold and iron are taken up, and afterwards separated from the residuum by the aid of a certain quantity of water, and the gold is afterwards precipitated from this solution by sulphide of hydrogen. To prevent the admixture of iron at this stage, a few drosses of hydrochloric acid is added to the solution before the sulphide of hydrogen is introduced. The auriferous compound having been separated from the liquor, is washed and heated in an open porcelain crucible, to drive off the sulphur, after which the gold is reduced to the metallic state by fluxing it in the usual way.

This simple and ingenious method, which has made it worth while to reopen the Reichenstein mine, is equally applicable to the vast quantity of refuse accumulated near many other old works.

METALLURGICAL OPERATIONS.—Fusion.—When the gold is received from the *gold-washer*, in the shape of gold-dust, or when it has been separated from its ores by amalgamation or otherwise, it has now to be subjected to a series of metallurgical operations to obtain it in a state of perfect purity. The first of these operations is that of fusion with borax, and casting the metal into ingots, by which it is obtained in a convenient form, and freed at the same time from earthy and other impurities. For this purpose, the gold dust from the washings, or the spongy gold obtained by amalgamation, is mixed with a little dried borax, and is introduced into a black-lead crucible, which has been previously heated in a common melting furnace. After the fusion of the metal, a slag, consisting of the grosser impurities, accumulates on the surface; this must be thickened by the addition of a little bone-ash, and then skimmed off. The metal is now cast into bars, by being poured into iron ingot-moulds, which should be previously warmed, and oiled, by wiping the internal surface with a piece of tow dipped in sweet oil. It is an old practice, now discarded by some metallurgists as useless, to add to the metal, when thoroughly melted in the crucible, a small quantity of corrosive sublimate; the contents are then well stirred, and, in consequence of the volatilization of the sublimate, effervescence takes place. That this is attended with no injurious effect seems to have been fully established by a long experience, and that it may even be productive of benefit is probable, by bringing to the surface any extraneous matter which might be detached from the interior of the crucible, and so permitting its removal along with the slag. The crucibles which have been used in a series of such operations, retain a portion of gold, which renders it important to preserve them, with a view to the subsequent extraction of the precious metal by smelting.

SMELTING OF GOLD ORES.—Although the readiest method of extracting the gold from rich alluvial sands

is by repeated washings, in the manner already described, and although in the treatment of quartz rock, iron pyrites, and other auriferous minerals, the method involving the tedious operations of pounding, washing, and amalgamation is usually adopted, yet, in the latter case, the same object may be accomplished by direct *smelting*—a term technically applied to a process, or series of processes, by which a metal is extracted, by the agency of fire, from the substances with which it may be combined or mixed in nature. It is well known that by this method iron is extracted from its ore in the blast furnace, and some years ago a Russian gentleman, named ANOSSOW, even proposed to smelt in this manner the auriferous sand of the Ural, alleging that a much larger quantity of gold could be so obtained than by the most skilfully conducted process of washing. His method consisted in smelting the sand with iron, the latter being employed simply as a vehicle to collect the gold, or to perform, in its melted state, the same part as mercury in the processes already described. When the gold was obtained in this state of combination, the mass was exposed to the action of sulphuric acid, by which the iron was dissolved and the gold remained in the insoluble residue. From some experiments which were made at the Museum of Practical Geology in London, it was found that, if it were advantageous on the score of economy, cast-iron might really be so applied; and that when it is melted with gold, an alloy seems to take place, from which the greater part, if not the whole of the gold may be extracted by again melting the alloy in contact with lead, which abstracts the gold. With regard to ANOSSOW's process, experiments were reported to have been made on the large scale, which had perfectly succeeded; but a strong proof of its want of success is the fact that it has never been practically adopted.

Of late years much has been said and written respecting the smelting of what has been called *gold quartz*, or, in other words, the extraction of the metal from the quartz in the furnace. The Editor, therefore, in proceeding to explain the common method of smelting, will assume, in the first place, that quartz or silica is the auriferous ore which it is proposed to subject to this operation. From the well-known infusibility of this substance, it is evident, that mere exposure to the strongest heat of a blast-furnace, without the addition of a flux, would be of no use; for, although the gold would be melted, it would remain in the quartz, and no separation of the precious metal would take place. Even supposing the quartz to be first reduced to powder, the gold is present in too small quantity to separate from the infusible mass, and sink to the bottom. It is therefore necessary to add some substance which, at a high temperature, shall combine with the quartz, and produce a fusible compound, in which case the gold, more especially if combined with some other heavy metal, will, in virtue of its high specific gravity, fall to the bottom of the vessel.

The best flux for silica is carbonate of soda, but this is too expensive to be employed on the large scale. Lime, therefore, aided by the addition of oxide of iron, is usually employed for this purpose. Lime alone, or lime and clay in certain proportions, will combine with

quartz at a high temperature, and produce a fusible slag. Oxide of iron alone will also suffice. When practicable, it is desirable to obtain the oxide of iron by roasting auriferous pyrites, such as that found in California or the Tyrol, for then the proportion of gold is increased by that contained in the pyrites. Whatever flux be employed, it is necessary, in the first place, to reduce the quartz to a comparatively fine state of division, otherwise a considerable loss of time and waste of fuel would be incurred in effecting the perfect combination required to ensure the complete separation of the gold. Even in smelting, therefore, the crushing or pulverizing process is not dispensed with. Assuming that lime and oxide of iron are the fluxes employed, and supposing the pulverized ore to have been partly concentrated by washing, these substances are mixed in about equal proportions, and raised to a white heat in a blast or reverberatory furnace. When oxide of iron is employed as the flux, the reverberatory furnace is to be preferred, because in the blast-furnace a considerable portion of the oxide would be reduced, and a corresponding quantity of metallic iron liberated, long before the mixture attained the degree of heat requisite for the combination of the silica with the oxide.

The product of the combination is a fusible *slag* or glassy substance, through which the gold, also in a melted state, tends to sink to the bottom of the furnace. But as the portion of this metal present even in a large quantity of ore is very small, compared with the bulk of the materials through which it is now diffused, it would be difficult to collect it *per se*, without very serious loss, in a crucible, and still more so in a furnace, whether reverberatory or blast. The operation is therefore materially assisted by adding another metal which shall combine with, and absorb, the whole of the gold, and from which the latter can afterwards be easily separated—some metal, in short, which shall serve the same purpose at a high heat, as mercury serves at the ordinary temperature. Of all metals, lead is found to be the best-adapted for this purpose, not only on account of its readily combining with the gold in a melted state, but also as offering peculiar facilities for its subsequent separation from that metal. Lead has, therefore, been uniformly employed in the processes hitherto generally adopted for smelting gold ores. The lead may be added to the mixture of ore and flux, either in the metallic state, or in one or other of its combinations, from which the metal may be set free. The materials most commonly employed to furnish the lead are litharge and galena—the former the protoxide, and the latter the native sulphide of that metal—although the rich slags obtained both from the smelting furnace and ore-hearth are also occasionally used. When litharge is chosen as the medium for the introduction of lead, it must be mixed with charcoal, small coal, or coke-dust, in order to determine the reduction of the necessary quantity of lead to the metallic state; but when galena is used, it is mixed with scrap-iron, for the purpose of combining with the sulphur, and setting the lead free. The lead-slag which comes from the ore-hearth or the reverberatory furnace, is generally the most convenient and least expensive

material, as it contains a considerable per-centage of lead, and is readily prepared for use by grinding it to powder under the edge-roll, and mixing it with charcoal or other carbonaceous matters. In this case, also, it is important to add some scrap-iron to combine with any sulphur which may be present in the slag. Whichever of these substances be employed, the lead evolved, under the conditions mentioned, percolates through the mass, and subsiding by virtue of its high specific gravity to the bottom of the furnace, carries along with it any particles of the precious metal it may meet with in its course. The lead is afterwards separated by *cupellation*—a process to be explained shortly.

Smelting with Iron Pyrites.—Instead of directly employing lead as the means of concentrating the gold ores, a method has been practised in Hungary, in which iron pyrites, generally itself containing a portion of gold, is used with economical effect for the same purpose. When this mineral is heated to a certain temperature without access of air, it loses exactly half of its sulphur, and becomes converted into a fusible sulphide of iron, such as is produced by bringing a roll of sulphur in contact with a bar of iron raised to a white heat. Let it be assumed, therefore, that the ore consists of a mixture of auriferous iron pyrites and quartz, and that this ore is mixed with the appropriate flux for the quartz, as already described, and exposed to the requisite heat,—in this case a slag will be formed, and the sulphide of iron will unite with the greater portion of the gold present, forming a heavy regulus, which will subside to the bottom. The stratum of sulphide of iron thus found beneath the surface of the slag and scoriæ produced by the fusion of the earthy and siliceous gangue, is technically termed a *matt*. If this matt, containing the gold, be now roasted, or *oxidized by heating it with free access of air*, whereby it is deprived of a further portion of its sulphur, and the product be mixed with a fresh quantity of crude auriferous pyrites, and smelted again, a second matt will be obtained, which will contain the gold from the first and second charges of the auriferous ore. This process may be repeated a third, fourth, or any number of times, until the precious metal has been sufficiently concentrated in the substratum of sulphide of iron to admit of its profitable extraction. The last matt, containing the whole of the gold which has accumulated from the successive charges, and brought, therefore, to any required richness, is then fused with metallic lead, litharge, or with a mixture of galena and metallic iron. The gold is abandoned to the liberated lead, from the top of which the impoverished sulphide may be readily skimmed off.

By this process, the gold is obtained in a more concentrated form, or mixed with a smaller proportion of lead, than when the latter is used directly as the means of separating and collecting it from the smelted ore. Still as the lead must be used for its final separation from the ore in all cases—even when the gold has been concentrated by washing and amalgamation—the employment of the iron pyrites in the manner above-described is only attended with advantage when it constitutes part of the ore itself, or when it can be readily and cheaply procured in sufficient abundance. When

it forms a principal ingredient in the ore, it is manifestly highly advantageous, in point of economy, to employ it as a vehicle for the concentration of the precious metal, while it contributes at the same time to increase the amount of the product.

Patent Smelting Process.—Some years ago a patent was secured for another smelting process, invented by Mr. LONGMAID, which consists in separating the gold from the quartz or siliceous ore, by introducing plates of wrought-iron into the melted mass. The quartz is first crushed to a fine powder, and fluxed with a mixture of lime and oxide of iron, as usual. Into the fused mass thus obtained, plates of wrought-iron are from time to time introduced, and withdrawn when their surface is found to be coated with a film of gold. The plates are then plunged into a vessel of melted lead, which dissolves off the precious metal, and afterwards again put into the furnace. This process is constantly repeated till the whole of the gold is extracted from the ore, and it is said to be thus obtained both more economically, and in greater proportion, than by the usual process of washing and amalgamation; but the Editor is not aware that this method has yet been extensively practised.

CUPELLATION.—The next metallurgical operation is the extraction of the gold from the lead, and this has been performed from the most remote antiquity by a process termed *Cupellation*. This process, which is very simple in principle, is, at the same time, one of the most elegant chemical operations ever invented. It depends on the circumstance that when silver and gold are exposed in a state of fusion to the action of the air or oxygen, they neither give off perceptible vapors nor are sensibly oxidized—they remain, in short, unaffected; whereas, under similar circumstances, lead and almost all the other metals are oxidized with greater or less rapidity. There is also an important peculiarity connected with lead, which renders it the only metal, excepting bismuth, applicable to the process of cupellation. This peculiarity consists in the circumstance, that the white oxide of lead, known as litharge, is fusible at a bright red heat, and in this state liquefies and absorbs into its mass any other metallic oxide with which it may happen to be in contact, but which, without the influence of the oxide of lead, would remain unliquefied by the heat. For example, if the oxide of copper be present, this oxide, which is a fixed infusible substance at the temperature of a common furnace, is taken up by the melted oxide of lead; and if the latter can be separated from the gold and silver, the oxide of copper will be expelled along with it.

This separation may be effected by different methods, but particularly by means of bone-ash, which possesses the peculiar property of absorbing the melted litharge, even when mixed with a certain proportion of other oxides, whereas it remains impermeable to the unoxidizable metals. Hence, if a vessel be formed of pounded and compressed bone-ash, and into this vessel a compound be introduced consisting of a mixture of litharge or oxide of lead, oxide of copper, and native gold, which always contains a certain proportion of silver; and if this mixture be exposed to the powerful heat of a furnace, the whole will be reduced to a state

of fusion; the oxide of lead, in melting, will combine with and dissolve the oxide of copper, and both will be absorbed by the bone-ash, while the mixture of gold and silver will remain in the vessel, melted by the heat, but otherwise unaffected. Hence it follows that gold and silver, or a mixture of the two, may readily be deprived of copper or any other oxidizable metals by cupelling them with oxide of lead. For this purpose it is not necessary to employ the oxide itself in the first instance. When metallic lead is heated to a temperature above its melting point, it rapidly combines with the oxygen of the air, the product being in the first place yellow oxide of lead, which appears as a scum on the surface; and when the temperature is raised to about bright redness, this oxide is converted into litharge or the white fusible oxide, which immediately melts. Pure copper requires not less than sixteen or seventeen times its weight in lead to be absorbed in the manner above-mentioned.

A vessel of bone-ash, formed for this purpose, is termed a *cupel* or *test*; and in using such vessels for *assaying*, the absorptive power of the cupel is the only agency employed to separate the gold from the lead and other oxidizable metals, as will be explained afterwards. It is otherwise in cupellation on the large scale; in this case the cupel is soon saturated, and the greater part of the litharge is expelled by a different method.

The English method of cupellation or refining is as follows:—A piece of bar-iron, about half an inch thick and four inches deep, is bent into the form of an oval hoop, and the ends of the bar are welded together. The greater diameter of this hoop, which is destined to form the containing circumference of the cupel or test, may be about four feet, and its lesser two feet six inches; but the dimensions vary considerably according to circumstances. On the lower part of the hoop are fixed a series of four or five flat bars of iron, arranged parallel to each other in the direction of the short diameter. The first of these is placed about nine inches from one end of the oval, and the others at about equal distances between this bar and the other extremity. The hoop is then placed with the cross-bars downwards upon a solid floor, and a quantity of pounded and sifted bone-ash is beaten firmly into it with a mallet or rammer until it is entirely filled, or the bone-ash is level with the upper edge of the hoop. The bone-ash employed for this purpose is mixed with about one-tenth, by measure, of fern-ashes, or one-fortieth by weight, of American pearl-ashes, and moistened sufficiently to become coherent by pressure. The fern or pearl ash has the property of giving greater consistency to the bone-ash when heated. When the hoop or frame has been well filled with this mixture and solidly beaten down, the surface is carefully scooped out with a trowel all round the centre, so as to form a shallow concavity of about two inches and three-quarters in depth, leaving a wall of bone-ash all round, about two inches in thickness at top and three inches at bottom, except at one end, where a thickness of five inches is left; whilst the thickness of the sole itself is reduced to one inch above the upper surface of the iron cross-pieces. At that end of the test where the wall was left five inches thick,

and which is termed the *breast*, a segment of the bone-ash, contiguous to the hoop, is removed.

This apparatus is represented in Figs. 229 and 230, of which the former is a plan, and the second a longitudinal vertical section of the cupel or test. In these drawings, the letters *A A* denote the iron hoop; *a a*, the

Fig. 229.

Fig. 230.

transverse bars; *E* indicates the cavity in the bone-ash; *B*, the breast; and *F*, the space where the bone-ash is removed between the breast and the iron.

When fully prepared, the test is allowed to dry, and is then placed in a furnace, constructed in all respects like a common reverberatory, except that a space is left open in the bed of the furnace to receive the test, and that the long axis of the arch is very short. The test, in fact, forms the bed of the furnace, in which it is adjusted with the long diameter transversely. It is supported in its place by an iron ring built into the masonry, or by iron bars placed underneath, between the two walls of the furnace. The fire-place of a cupelling furnace is usually about two feet in breadth, and two feet six inches in length. This is separated from the body or bed of the furnace by a fire-bridge eighteen inches in breadth, so as to allow the flame and heated air to pass directly over the surface of the cupel, from whence it escapes through separate flues into a high chimney. At the side of the furnace opposite to the breast of the cupel, the nozzle of a pair of large double bellows, or a fan-blast, is introduced.

When the cupel is inserted and the furnace lighted, the heat must be applied in the first place with much caution; for the cupel or test, if exposed suddenly to a high temperature before it has become sufficiently dry, is liable to split and fall to pieces. In the meantime, the lead containing the gold and silver, and which, from this circumstance, is termed *rich lead*, is brought to a state of fusion in a cast-iron pot, set in brickwork at the side of the furnace; and when the test has been cautiously raised to a cherry-red heat, the rich lead is laded into it till nearly full. Oxidation now proceeds rapidly. At first the lead becomes covered on the surface with a yellow or grayish dross; but on further raising the

heat, the surface of the bath uncovers, and a film of melted litharge begins to appear. Part of this litharge sinks into the bone-ash of the test, which it soon saturates. The blowing apparatus at the back of the test is now set in motion, and forces the litharge as it forms forward to the breast, *B*, across the surface of which a channel is cut, through which the litharge begins to flow, and runs over at the end through the vacant space, *F*, into a movable iron pot, placed on the floor for its reception. By this means the oxide of lead is prevented from coming in contact with the iron frame of the test, on which it would exert a powerfully-corroding action. The current of air introduced at the back of the cupel not only assists in clearing away the litharge, but readily supplies the amount of oxygen necessary for its rapid formation. In proportion as the litharge flows away, more of the melted lead is gradually supplied to the test, which is done by lading it into a channel from the pot outside the furnace.

After a certain period, the channel first formed in the breast, *B*, becomes much corroded; it must then be stopped, and a second and third channel successively formed for the same purpose. In this manner the operation may be continued until six or eight tons of the rich lead have been refined on the same test. Sometimes, however, two tests are employed, the first to concentrate the lead, and the second to separate it entirely from the precious metals. In this case, when the lead has been so far concentrated in the former that the whole of the gold and silver contained in the alloy may remain in combination with only two or three hundredweight of that metal, a hole is made through the bone-ash of which the bottom is composed, and the concentrated lead is received into a pot which is placed below. The tapping-hole is then closed with a pellet of moistened bone-ash, and a fresh charge of the original rich lead is concentrated in the same manner. When a sufficient amount of concentrated lead is thus accumulated to yield, as ascertained by assaying a small portion, from one to two thousand ounces of the precious metals, the whole is again melted down, and submitted to a second cupellation in another test, in which the operation of refining is completed.

Towards the conclusion of the operation some striking appearances are presented. As soon as the last portions of lead are removed, the liquid alloy of gold and silver in the cupel suddenly assumes a bright and resplendent surface; and, if the gold present is mixed with a considerable amount of silver, the surface of the mass, as it cools, is suddenly thrown into agitation; cones, or little craters, sometimes several inches in height, are thrown up, from which oxygen gas escapes with violence, projecting particles of silver with considerable force. This phenomenon is termed *spitting*, or sometimes *vegetation*, from the beautiful arborescent forms which are presented; and arises from the circumstance that metallic silver, when melted, has the property of temporarily combining with or absorbing much more than its own volume of oxygen, which escapes or is ejected with violence at the moment of solidification. For reasons especially connected with the final process of *parting*, and which will be afterwards explained, there

is almost always introduced into the alloy, before cupellation, a comparatively large amount of silver, so that the phenomena above described are almost uniformly observed at the conclusion of that process. Even in the cupel, the presence of a considerable proportion of silver is important, for the purpose of diluting the gold, and so diminishing the chance of loss.

After the cupelling, the test, with its cake of alloy of gold and silver, is withdrawn from the furnace; the metallic mass is removed and cleaned from external impurities; and the bone-ash, saturated with litharge, and any other oxide that may be present, is knocked out and preserved for subsequent treatment, as it contains not only a considerable quantity of lead in a state of oxide, but also a small proportion of silver.

On the Continent, the process of refining is conducted without the use of a cupel, properly so called. No bone-ash is employed. The test, if it may be termed so, is the bed of the furnace itself, which consists of a kind of marl, firmly beaten down into a circular cavity, sloping from the sides to the centre, and allowed to dry. The roof of the furnace, which consists of a flat dome of bricks, built in a strong circular hoop of bar-iron, is movable by means of a crane. Several tons of lead are introduced at once, and after the roof has been replaced, the blast is transmitted through one or more apertures in one side of the furnace; the whole mass of metal is then worked off continuously, without any addition, till the lead is entirely removed, and the alloy of gold and silver is left fine.

PARTING.—The final operation of separating the silver from the gold, is termed *parting*, and is generally performed in this country by means of nitric acid, which dissolves the silver, without attacking the gold. On the Continent, the same effect is produced with *hot sulphuric acid*. In assaying operations, nitric acid is always employed, and therefore the precautions necessary to be observed in this case will be fully explained in connection with the subject of *assaying*. In the meantime, the process with sulphuric acid, as practised on the Continent, will be first detailed.

1. *By Sulphuric Acid.*—It is only of late years that the use of sulphuric acid for this purpose has been generally introduced on the Continent, in consequence of its being now manufactured so much cheaper than nitric acid, which was formerly the only acid employed. The operation is performed in a very simple manner, and if any copper has been left in the alloy, it is separated along with the silver. It is true that the copper should be entirely expelled by the process of cupellation; but, as this process is practised on the Continent, a considerable amount of that metal often remains in the mixture; and its presence is by no means injurious, but is rather useful, in the subsequent operation of parting with sulphuric acid. It is true that if too much copper be present, a sulphate is produced, of which only a limited proportion will dissolve in the concentrated acid. The proportion of gold also must be less, as compared with the amount of the silver, than when nitric acid is used. Experience has shown that the alloy should not contain more than one-twentieth part of copper; and that the proportion of the gold to the silver should not exceed one-fifth; whereas, with nitric

acid, it is sufficient if the weight of the silver amount to about three times that of the gold.

When the silver is not already present in the required proportion, which is never the case with native gold, the requisite excess must be introduced; for, when the amount of gold exceeds the proportions above-stated, the particles of silver are so enveloped in that metal as to resist for a long time the action of the strongest nitric or sulphuric acid. In the process of assaying, the proportion of rather less than three parts of silver to one of gold is very closely adhered to, for reasons to be afterwards mentioned; but in operating on the large scale with sulphuric acid, the proportion of the gold to the silver may vary from one-fifth to one-tenth, without inconvenience; and DUMAS states that the operation may be conducted with profit when the ratio of the gold to the silver does not exceed 1 : 1000.

The alloy being prepared in the requisite proportions, which is generally done by introducing the excess of silver before cupellation, is melted in a crucible, and granulated by pouring it into cold water. For one part of the granulated alloy, three and a-half parts of concentrated sulphuric acid are taken, and the mixture is put into a platinum vessel, which is then introduced into the furnace. The vessel should not be more than two-thirds filled, to guard against the effects of effervescence, which might throw out part of the liquid. It is then covered with a platinum hood, provided with a beak or tube for conveying the gases and vapors into a condensing apparatus. The capacity of the platinum retorts varies, and there is usually an assortment of different sizes, for treating alloys of different qualities, without the necessity of mixing them. After two or three hours' boiling, varying the time according to the size of the retorts, the silver, and any copper that may be present, are completely dissolved.

On the first application of sulphuric acid to this purpose, the operation was performed in iron retorts. Vessels of platinum were afterwards introduced, as this was considered to be the only metal which could perfectly resist the action of hot and concentrated sulphuric acid. Afterwards, however, the enormous expense required for a complete assortment of platinum retorts, induced the attempt to return to the use of iron, and successful experiments were made by M. TOCCHI, which proved that iron retorts might be safely employed, though platinum is still in use in many establishments. It was found that the very concentration of the acid presented, of itself, an obstacle to the precipitation of the silver or copper by the iron; and, further, that the interior surface of the retort acquired a coating of silver, so that the iron and the liquid soon ceased to be in contact. This point has not been sufficiently studied; but the fact has been placed beyond doubt that the operation succeeds very well in iron vessels, and accordingly, in many refining establishments, no other are employed.

It cannot fail to be observed that, assuming the proportions above given, the quantity of sulphuric acid is much greater than would be strictly necessary to convert the silver and copper into sulphates. Supposing the alloy to be as poor as possible in gold, theory would

indicate the following quantities of acid as being sufficient for this purpose:—

	Parts.	50 would require	Parts.	155 sulphuric acid.
Copper	949	"	861	"
Silver	"	"	"	"
Gold	1	"	0	"
Alloy	1000	"	1016	"

But as the amount of sulphuric acid employed is actually 3500 to 1000 of alloy, there is an excess of about 2500 of acid, intended to hold the sulphates, and especially the sulphate of copper, in solution.

When the silver and copper are completely dissolved, the retorts are withdrawn from the fire, and the solution is left to cool, that the gold may settle to the bottom. The liquid is then decanted; the gold, which remains in the vessel, is carefully washed, and the waters employed in this operation are added to the sulphate solution. Lastly, the purified gold is melted, and after being cast into ingots, is ready for commerce.

The acid liquor, containing the sulphates, is poured into a leaden boiler, containing water and copper shavings. Heat is applied, and the sulphate of silver is soon completely decomposed. The precipitated silver is collected, and submitted to repeated washings, always adding the water to the boiler, for use in the next operation. Lastly, the silver is dried in a small iron pan, and is then melted in a crucible, to be cast into ingots.

The acid solution, which now contains only sulphate of copper, is evaporated in lead boilers till it is fit to crystallize. It is then put into the crystallizing pans, and the mother waters are further evaporated, to obtain more crystals. This process is continued till the liquid becomes very concentrated, and consists almost entirely of sulphuric acid. In this state it is termed *black acid*, on account of its color, which is due, in great part, to organic matters, dust, and other impurities, which fall in it during the evaporation in the crystallizing pans. The black acids, purified by concentration, may either be employed to repeat the same operation, or turned to useful account in different manufacturing processes, which do not require that the sulphuric acid should be pure and highly concentrated.

2. *By Nitric Acid.*—The operation of parting is performed with nitric acid in much the same way; but all the details of the process with this acid will be minutely explained in connection with the subject of assaying, for which it is uniformly used.

3. *By fusion with Sulphur.*—Another method of separating the gold from the silver, which is sometimes practised with alloys containing but very little gold, is by fusing the granulated alloy with three-tenths of its weight of sulphur; this combines with the silver, and forms a liquid sulphide, in which the finely-divided gold remains suspended. A small quantity of litharge is then added, which gives rise to the formation of sulphurous acid and sulphide of lead, and again separates a portion of the silver, which then combines with the gold, forming an alloy richer in the latter metal. This alloy, by its greater gravity, sinks to the bottom of the crucible, and, after cooling, is separated by the hammer from the superincumbent mixture of sulphide of silver and lead. When this mixture, which is

termed *plachmal*, is fused with a small quantity of litharge, it yields silver, which for the most part still contains a little gold. The richer alloy which subsided to the bottom of the crucible, is treated repeatedly with sulphur in the same manner, till the proportion of gold is raised to one-fourth, after which the final separation of the silver is usually effected with nitric or sulphuric acid. It will be observed that this process is similar in principle to the method already described for concentrating auriferous pyrites.

4. *By fusion with Sulphide of Antimony.*—In this case, the alloy is mixed with two parts by weight of sulphide of antimony, and fused, with constant stirring, in a crucible, which should be previously glazed with borax. By this means sulphide of silver is formed, and the gold combines with the antimony, forming a lower stratum of alloy, which is afterwards separated from antimony by simple ignition in the air, or by fusion with nitre. If the amount of silver in the original alloy exceeds one-third, a proportional quantity of sulphur must be added in the crucible. The sulphide of silver forming the upper stratum retains a small portion of gold, to separate which it is again twice fused with sulphide of antimony, and this is again removed by ignition or fusion with nitre. The same operations are repeated on the whole amount of antimonide of gold thus obtained, and the antimony is finally removed either by fusing the antimonide alone, while air is blown upon it, or by fusion with three times its weight of nitre. Sometimes it is melted into a mass by heating it with three-fourths of its weight of borax, one-fourth of nitre, and one-fourth of glass.

5. *By Cementation.*—Another method, which is practised in America, consists in arranging the granulated alloy in alternate layers, with a mixture of two parts of brick-dust and one part of chloride of sodium in *porous crucibles*, which are exposed to a low red heat in a wood fire for a period varying from twenty-four to thirty-six hours. The aqueous vapor from the wood permeates the crucibles, and acts upon the salt in such a manner as to separate hydrochloric acid, which then forms chloride of silver with evolution of hydrogen. The chloride of silver, together with the chloride of sodium, sinks into the brick-dust, and the gold obtained after washing, contains not more than from one-tenth to one-eleventh of silver.

In this case, without the brick-dust, the conversion of the silver into chloride would be only superficial, because the chloride first formed would protect the inner portions of the alloy from the action of the hydrochloric acid. But when the alloy is enveloped in brick-dust, the chloride of sodium is partly decomposed by the silica, yielding silicate of soda and hydrochloric acid; the latter converts the silver into chloride, which then fuses with the rest of the chloride of sodium, and this, sinking into the brick-dust, leaves a new surface of alloy exposed to the action of the hydrochloric acid.

The reader will observe that the three methods last mentioned are all more or less imperfect in their results, and that for the complete separation of the silver, recourse must always be had to the action of sulphuric or nitric acid.

ALLOYS OF GOLD.—STANDARD GOLD.—By the preceding series of mechanical, metallurgical, and chemical operations, gold may be brought to a state of nearly absolute purity; but in this state it is too soft to be employed with advantage in the arts, or for the purposes of the coinage. Gold is therefore almost always alloyed with a greater or less proportion of some other metal, except when it is found in the shape of the finest gold leaf, which requires for its proper manufacture the highest possible purity, because, although it readily forms alloys with most of the other metals, its malleability is greatly impaired by their presence in even a very small proportion. With some metals this effect is very remarkable; even one two-thousandth part of antimony, bismuth, tin, or lead, will render the gold quite brittle. At the same time, as a natural consequence, its hardness and sonorousness are increased.

The only alloys of gold of any importance in the arts are those formed with silver and copper, which tend to increase its hardness and durability, and are used also by jewellers to give the gold different tints, according to the proportions employed. It singularly happens that these are the metals with which it is chiefly combined in the native state, although it is likewise found associated with iron, platinum, tellurium, and other metals.

Gold may be alloyed with silver in almost all proportions, and, by its combination with this metal, it becomes not only harder and more sonorous, but also more fusible. As the proportion of silver increases, the color quickly passes through pale greenish-yellow into white. The malleability of gold is less diminished by silver than by any other metal. The maximum of hardness is found in the alloy containing two parts of gold to one of silver. The *green gold* of the jewellers contains twenty-five per cent. of silver.

The most useful alloy of gold is that which is formed with copper, and this is the alloy which is used for coinage. The addition of copper renders gold redder, harder, and more fusible. The maximum of hardness is exhibited by an alloy of seven parts gold and one of copper. An alloy containing twenty-two parts of gold and one of copper has a density of 17.157. English standard gold contains 8.33 per cent. of copper, or one part of this metal to eleven parts of gold. In France, the standard gold contains ten per cent of copper. Gold contracts in the act of solidifying from a state of fusion, and cannot, in consequence, be made to receive sharp impressions by casting it in moulds. Coins are, therefore, stamped with a die, and plate is either stamped or embossed, and afterwards chased and carved, if necessary, by cutting tools.

Valuation of Gold Alloys.—In this country the standard of the alloys of gold is calculated in fractions of unity expressed in carats. Perfectly pure gold is taken as unity, and this is assumed to consist of twenty-four fractional parts termed *carats*, each of which is divided into four imaginary grains, and these are again subdivided into quarters and eighths. The carat is, therefore, ultimately divided into thirty-two thirty-seconds; so that unity, or absolute fineness, represented by twenty-four of these carats, may be con-

sidered as made up of $24 \times 32 = 768$ thirty-seconds. On this system, an alloy of gold, according to its composition, is spoken of as being so many carats fine, or so many carats and thirty-seconds of a carat. It has been stated above that the standard alloy of the English gold coinage contains eleven parts of gold to one of copper, or, in other words, twenty-two parts of gold to two of copper; it is, therefore, said to be twenty-two carats fine. If the alloy contained twenty-three parts by weight in the twenty-four, it would be twenty-three carats fine, or one carat *better than standard*. If, on the other hand, it contained only twenty-one carats, it would be one carat *worse than standard*; if it contained 18.5 of pure gold, it would be said to be eighteen carats, and sixteen thirty-seconds. The report of the assayer is always given in relation to standard. Fine or pure gold would be twenty-four carats fine, that is, there would be no alloy.

In calculation it is easier to use decimal fractions than the clumsy empirical system of counting by carats; and in estimating silver the decimal method has lately been introduced into the mint of this country by Sir John Herschel. In France the same method is generally extended to gold. Upon the decimal system, fine gold or silver is termed 1000.0, and the report upon any sample of alloy simply indicates the number of parts of pure gold or silver in 1000 which the sample contains. Unfortunately the English standard does not admit of expressing the amount of copper in a terminable decimal, the nearest convenient fraction being 90.91 of copper in 1000 of alloy. In France, the standard is conveniently expressed by 900 of gold to 100 of copper. This decimal standard admits of the ready comparison of gold alloys with other chemical compounds, because in analytical investigations the results are always sought with reference to the percentage or centesimal composition of the subject under examination; but, under the system existing in this country and on many parts of the Continent, it is often necessary to convert the per-centage into the corresponding value expressed in carats. The following table, which expresses the relation subsisting between a series of decimal fractions of unity and the carats and thirty-two thirty-seconds respectively, will be found convenient for immediately effecting the conversion:—

Thirty-seconds of the carat.	Decimal.	Carats.	Decimal.
1	0.001302	1	0.041667

JEWELLERS' GOLD.—The jeweller receives his gold in the form of ingots, which approach to absolute purity, or twenty-four carats fine. He begins his operations by alloying it with copper or silver, or both, in certain calculated proportions, either to reduce it to the legal standard, or to give it the particular color required. The following are the three standards fixed by the latest statutes enacted in France on the subject:—

1. *High standard gold*, consisting of nine hundred and twenty parts of pure gold in one thousand of alloy, which is equivalent to twenty-two carats, one thirty-second and one-half. This is the alloy usually employed by the French jewellers, and is nearly identical with the standard gold of the English coinage.
2. *French standard gold*, consisting of eight hundred and forty parts of gold in one thousand of alloy, or twenty carats, five thirty-seconds, and one-half. Sometimes it is reduced to only twenty carats.
3. *Common gold* is seven hundred and fifty parts in one thousand, or eighteen carats. The licence or *tolerance* allowed is three parts in a thousand.

In order that the gold may be easily worked, the alloy must be perfectly homogeneous, and the jeweller accordingly brings it to this state by repeated fusions. If the alloy has been badly made, and still exhibits a grainy appearance, with a liability to crack under the action of the hammer or between the laminating rollers, it must be again introduced into the crucible, and thoroughly fused with a mixture of borax and saltpetre.

In the *Dictionnaire des Arts et Manufactures*, the colors most commonly required in articles of jewellery, are stated to be composed as follows:—

Colors.	Composition
Yellow gold,	Pure or fine gold, 1000.
Red gold,	Fine gold, 750; rose copper, 250.
Green gold,	Fine gold, 750; silver, 250.
Dead-leaf gold,	Fine gold, 700; silver, 300.
Water-green gold, ...	Fine gold, 600; silver, 400.
White gold,	{ An alloy of gold and silver in which the latter predominates.
Blue gold,	Fine gold, 750; iron 250.

The last-mentioned alloy is somewhat difficult to prepare. It is obtained by introducing thick iron wire among the melted gold, and withdrawing the crucible from the fire as soon as the alloy is formed. When poured out and cooled, it should have no appearance of porosity. It is then forged, and formed into sheets or wires of different thicknesses.

Various shades of color are likewise given by the jeweller to articles or ornaments of gold, by the finishing process, which consists in exposing them to certain chemical agents, to dissolve out a portion of the copper or silver from the surface, without attacking the gold. By this means the surface of the article is made to appear like pure gold, which it really is, while below the

surface the quantity of copper or silver may be considerable. The liquor usually employed by the goldsmiths and jewellers for this purpose is a mixture of two parts of nitrate of soda, one part of chloride of sodium, and one of Roman alum, in three or four parts of water. The trinkets or other articles are kept in this solution, at the boiling point, from fifteen to twenty-five minutes, according to the shade required. They are then taken out, washed in water, and after burnishing with blood-stone, the operation is finished. The pickle, or sauce, as the liquor is termed, dissolves not only the copper or silver alloy on the surface, but likewise a certain quantity of the gold itself, and the articles lose, on the whole, about one-sixteenth of their weight by the operation. To recover the gold, the liquor is diluted with at least twice its bulk of boiling water, and a solution of very pure protosulphate of iron is poured into it. The precipitated gold is washed upon a filter, dried, and purified by fusing in a crucible, along with a mixture of equal parts of nitrate and bichlorate of soda. The other metals can likewise be recovered by very simple methods.

GOLD-BEATING.—The art of beating gold into thin leaves seems to have been known from a very remote period. The fact that the Hebrews were acquainted with it has been already stated,—and from the circumstance that, on the coffins of the Theban mummies, specimens of leaf-gilding are met with, in which the gold is so thin as to resemble modern gilding, it may be inferred that the Egyptians had carried the art to a high degree of perfection. This art is distinctly referred to by HOMER, and was practised extensively by the later Greeks, even to decorate the external sculpture of their temples and statues. PLINY states that after the destruction of Carthage the Romans began to gild the ceilings of their temples and palaces, and that luxury advanced on them so rapidly that, in a little time, even private and comparatively poor persons gilded the walls, vaults, and other parts of their dwellings. HORACE's remark, that *neither ivory nor gilded arch figured in his house*, is familiar to the classical student. PLINY further states, that one ounce of gold was extended to 750 leaves, each four fingers square. LUCRETIVUS compared the Roman gold-leaf to a spider's web, and MARTIAL described it as little other than a vapor; yet, according to PLINY's account, it must have been three times the thickness of the ordinary leaf-gold of the present time.

Experiments have been made to ascertain to what degree of thinness gold and silver could be reduced: it was found that one grain of gold was spread to the extent of seventy-five square inches, and the same weight of silver to the still more extraordinary dimensions of ninety-eight square inches. Taking one cubic inch of gold at four thousand nine hundred grains, it will be found that the gold was the three hundred and sixty-seven thousand five hundredth part of an inch in thickness, or about one thousand two hundred times thinner than ordinary printing paper. Thus, if three hundred and sixty-seven thousand leaves of gold were placed on one another they would constitute a pile only an inch high, while the same number of leaves of paper would form a pile half the height of

the Monument of London. The same *weight* of silver, though extended over a much larger surface, was thickest, owing to the difference in its specific gravity. In practice, the gold leaf is never extended beyond the one-two hundred and ninety thousandth part of an inch in thickness.

The late Dr. URE erroneously states, that the gold used in gold-beating ought to be of the finest standard. Alloy, he adds, hardens gold, and renders it less malleable; so that the fraudulent tradesman who should attempt to debase the gold would expose himself to much greater loss in the operation than he could derive of profit from the alloy. From this statement it might be inferred that nothing but fine or perfectly pure gold is used by the gold-beater, whereas, in point of fact, it is variously alloyed, according to the color required. Indeed, it is not uncommonly supposed, among the workmen employed in the business, that fine gold is incapable of being reduced to thin leaves; but this also is an error. It is simply objectionable for commercial purposes, on account of its greater cost, and also on account of the adhesion which takes place when one part of a leaf of fine gold touches another, thus causing a waste of labour, by the leaves being spoiled. For work, however, which is to be exposed to the weather, fine gold is the best, being more durable, and not liable to tarnish or change color.

A London gold-beater, Mr. E. S. MARSHALL, exhibited specimens of gold-leaf at the Great Exhibition of 1851, for which the prize medal was awarded to him. The specimens were twelve in number, and embraced a regular gradation in color from red to nearly white—namely, red, pale red, extra deep, deep, orange, lemon, deep pale, pale, pale pale, deep party, party, and fine gold. The deeper colors were alloyed with from twelve to sixteen grains of copper per ounce, but no silver, since any admixture of this metal with so large a quantity of copper would considerably impair the malleability of the alloy; the medium colors contained from twelve to twenty grains of silver, with from six to eight grains of copper, to the ounce; and, lastly, the paler leaves contained from two to not less than twenty pennyweights of silver to the ounce, but no copper, for the same reason that silver was omitted in the red or deep-colored golds.

The process of gold-beating is purely a mechanical operation, but involving as it does one of the most important applications of this precious metal, it will be necessary to give a short account of it. The first operation is the *casting of the metal into ingots*. For this purpose the gold, either pure or alloyed, according to the color desired, is melted in a crucible at a higher temperature than is simply necessary to fuse it, by which its malleability is improved. It is then poured into moulds previously heated and greased on the inside, and cast into flat oblong ingots, each about three-fourths of an inch wide, and weighing two ounces. The ingots, when taken from the moulds, are annealed in hot ashes, which cleanse them from grease and increase the malleability of the gold. When the ingot is cold, the French gold-beaters hammer it out to the thickness of one-sixth of an inch, and expose it at the same time to repeated annealings; but this operation,

termed the *forging*, is omitted by the English gold-beaters. The next process is the *lamination*, which consists in repeatedly passing the ingot between two rollers of polished steel, gradually brought closer together, until it is formed into a riband of one and a half inch in width, and ten feet in length, to the ounce. By this means the ingot is spread out to a surface of nine hundred and sixty square inches of the thickness of rather more than one-eight-hundredth of an inch. The next operation is the *beating*, for which purpose the riband of gold, after being annealed or softened in the fire, is carefully divided with compasses and cut up into pieces of the size of a square inch, each weighing about six grains; about one hundred and sixty of these are placed by means of wooden pliers between the leaves of a *cutch*, which formerly consisted of a packet of fine calf-skin vellum, but now it is usual to employ a tough paper manufactured in France. A case of strong parchment, open at both ends, is drawn over the cutch, and this is enclosed in a second similar case at right angles to the first, so as to cover the edges which the first had left exposed. The cutch is then beaten with a seventeen-pound hammer, upon a smooth block of black marble, supported on a strong bench, and surrounded on three sides by a wooden ledge, while the front is left open, and has a leathern apron attached to it, to preserve any fragments of gold that may fall out of the packet. The hammer is short-handled, and is wielded by the workman with one hand, while with the other he occasionally turns the packet over, to distribute the force equally. The elasticity of the packet causes the hammer to rebound, and lightens the labor of the operator. At intervals the packet is taken up, and bent or rolled between the hands, to overcome any slight adhesion between the leaves and the interposed paper or vellum; or it is taken to pieces to examine the state of the gold, and to shift the central leaves to the outside, and *vice versa*.

When the gold plates of one inch square are thus spread out into four-inch squares, or to nearly the size of the leaves of the cutch, which generally requires about twenty minutes' beating, the packet is opened, and each leaf of gold is taken out, and cut with a knife into four equal squares, thus increasing the one hundred and fifty pieces to six hundred of nearly the same size as at first. These are put between the leaves of another tool, called a *shoder*, made of *gold-beater's skin*. This substance is the cæcum of the ox, which is first doubled, then prepared with solutions of alum, isinglass, white of egg, *et cetera*, and after being beaten between folds of paper to expel the grease, is finally pressed and dried. The shoder is enclosed in parchment and beaten as before, but with a smaller hammer, about nine or ten pounds weight, till the squares of gold are again extended to nearly the size of the skins. The shoder requires about two hours' beating for this purpose. During this period, the packet must be often folded, to render the gold as loose as possible between the membranes. As all the leaves do not spread quite equally, the shoder is beaten upon after the more expanded leaves have reached the edges, the effect of which is, that these come out of the edges in the shape

of dust, and this allows time for the smaller leaves to reach the full size of the shoder.

The packet is now opened, and the leaves of gold, being spread on a cushion, are again subdivided into fours, by means of two pieces of cane cut to very sharp edges, and fixed down cross-wise on a board. This rectangular cross being applied on each leaf, with slight pressure, divides it into four equal portions, and is preferable to a steel knife, to which the gold, in its now attenuated state, would be liable to adhere. The two thousand four hundred squares thus formed are separated into three parcels of eight hundred each, and the squares of each parcel are placed in another shoder or mould composed of gold-beater's skin, enclosed in the parchment cases, and beaten as before. This is the last and most difficult stage of the process. The mould must be made of the finest skins, about five inches square; and on the fineness of the skin, and the judgment and dexterity of the workman, the perfection and thinness of the leaf of gold depend. A seven-pound hammer is now employed, and after two hours' beating, the gold is reduced to the one hundred and fifty thousandth of an inch in thickness, and begins to transmit the rays of light. When the gold is quite pure, or but slightly alloyed, it transmits the green rays, but in gold highly alloyed with silver, the pale violet rays are transmitted. After being hammered another two hours, the leaves acquire the tenuity of ordinary leaf-gold, and average from three to three and a half inches square. The three beatings and two quarterings expand the gold to an area about one hundred and ninety times greater than it had in the form of a riband, and one hundred square feet of it weigh only an ounce. It is true that an ounce might be hammered to cover an area of one hundred and sixty feet; but in this case the gold would be too much attenuated for common use, and the extra labor and care required would not be compensated by any corresponding advantage. After the last beating, the leaves are lifted one by one with a delicate pair of long pincers, made of white wood, and are spread out on a leathern cushion by blowing them flat with the mouth. Broken or blemished leaves are rejected; the good ones have the ragged edges cut off with a square frame of sharp cane, which reduces them all to a uniform size, and are then placed in a book, the leaves of which have been rubbed with red ochre, to prevent the gold from adhering. Each book is capable of holding twenty-five leaves, and in this form the gold-leaf is sold for gilding picture-frames and books, and for the various ornamental purposes to which it is applied in the arts.

In this country the art of gold-beating was long confined to London, where it has been carried to higher perfection than in any other part of the world; but, of late years, efforts have been made on the Continent, with the aid of English gold-beaters' skin, to emulate the beauty and fineness of the English product; and the art is now practised successfully in different large cities in England, as well as in Scotland and Ireland. Latterly, machinery has been applied to supersede the arduous manual labor of gold-beating with the hammer, and machines for this purpose were sent to the Great Exhibition from France and the United States.

There was also exhibited a specimen of leaf-gold, manufactured in London by means of steam machinery; and there is little doubt that the article, so manufactured, will ultimately supersede the product of manual labor.

GILDING.—This is the art of applying a superficial covering of gold to articles of wood, metal, *et cetera*, chiefly for the purpose of ornament, but sometimes also for utility, as when it is essential that the article should be preserved from tarnishing. Gilding is practised by various methods, the principal of which may be classified under the following heads, namely: 1. Mechanical gilding with gold-leaf for wood, leather, *et cetera*; 2. Chemical gilding, properly so called, which is practised on metallic substances, and includes wash-gilding, or gilding by amalgamation; gilding by immersion and various other processes; 3. Electro-gilding, commonly known as the electrolyte.

1. *Mechanical Gilding*, or gilding on wood with gold-leaf, is of two kinds, distinguished as burnish-gilding and oil-gilding.

In *burnish-gilding*, the process may be exemplified as applied to a picture-frame. In this case the gilder receives from the joiner a bevelled moulding twelve feet in length, which he prepares for gilding by a number of preliminary coatings of size, mixed with different substances. He first gives it a priming of hot size and whiting, this mixture being laid on in a somewhat fluid state, and therefore termed *thin-white*. It is prepared by melting the size in an earthen pipkin, and stirring in the whiting in fine powder by small portions at a time. When this first coating is dry the surface is examined, and all holes and irregularities are filled up with a mixture of whiting and size, made of the consistence of putty, but containing no oil. The moulding then receives four or five layers of a mixture similar to the first, but of greater consistence, and therefore termed *thick-white*, allowing time between each layer for the work to dry. While each of these last coatings is still wet, the fine work of the moulding is kept open by means of chisels, gouges, and other tools for the purpose. Sometimes two thick-whites are laid on successively, without allowing the first to dry, and are then worked into the shape of the moulding by hard stones of the required form. The whiting is now from one-sixteenth to one-twelfth of an inch in thickness, and is trimmed to remove the unevenness at the edges, after which the entire surface of the moulding is smoothed with pumice-stone, formed to fit exactly into the various parts, which are slightly wetted to promote the smoothing effect. The final polish of the whiting is given with glass-paper.

The moulding is now ready to receive the gold-size, which consists of pipe-clay, red chalk, black lead, suet, and bullock's blood. Of this mixture, which is sold to the gilder in a tenacious mass, rather softer than butter, a portion is taken and melted with common clear thin size; and while still slightly warm, is laid on with a brush, and with great nicety of hand.

The next operation is the gilding, for which several tools are required,—a leathern cushion to receive the gold-leaf, a knife for cutting it into different sizes, and a little instrument, termed a *tip*, for laying the leaf on the moulding. This last instrument consists of two

pieces of card glued together, with the ends of a row of camel's hairs fastened between them, and projecting from one inch to one inch and a half. The gilder having moistened with water a few inches of the moulding about to be gilded, and having cut a leaf into stripes suited to the width of the part on which it is to be laid, touches one of these stripes with the tip, to the hairs of which it slightly adheres, and transfers it to the moistened part of the moulding. When the whole of the moulding has been thus covered, it is set aside to dry.

The next process is the burnishing, which is performed by rubbing briskly over the gold a piece of flint or agate. This greatly increases its brilliancy, and does not injure the gold-leaf on account of the foundation of gold-size and whiting which yields under the hand. The parts which are to be in *dead* gold or *matt*, are left unburnished, but over these parts a very thin, clear size is passed, and, when dry, the gold is carefully wiped with soft cotton wool. The work is completed by wetting the matt parts with a pencil dipped in clear finishing size. The moulding is then passed into the hands of the frame-maker, who cuts it up and forms it into a frame of the required size.

When the frame or other article to be gilt is somewhat richly ornamented, *oil-gilding* is used. In this case the moulding is first whitened as before, but is then made up to the required shape, and decorated with composition ornaments before the application of any further primings. In this state the gilder receives the frame, and his first operation is to wash it, in order to free it from oil or other impurities. He then gives it two or three coatings of thin-white, mixed with a little soft clay, and several additional coatings are given to the parts intended to be burnished. Two or three coats of a moderately strong size called *clear-cole* are now spread over the whole, after which the *oil gold-size*, consisting of a mixture of boiled linseed-oil and ochre, is laid on smoothly with a brush. After six or eight hours, when the oil-size has been partially dried, the gold-leaf is applied as before, except that in this case no water is used, the oil serving the same purpose. For deep ornaments, the gold is pressed in with cotton-wool, and in this case the gilding has to be repeated to remove the irregular fractures known by the gilders as *spiders' legs*. The work, which has still a ragged appearance, is now carefully gone over and smoothed with a brush—superfluous gold being removed from some parts and worked into others. This operation is termed *skewing*. The parts to be burnished are then treated as before, and finally the frame, after being dusted, is sized with clear size, and yellowed on the outside.

Another application of gold-leaf is to book-gilding. When the book is bound in leather, the back and sides to be gilt are first covered with a coating of isinglass, or white of egg, dissolved in a large proportion of water, and termed *glaire*. This is allowed to dry, and when the gold-leaf is about to be laid on, a woollen rag, slightly moistened with hog's lard or sweet oil, but so as to feel almost dry to the touch, is rubbed over the leather. This causes the adherence of the gold-leaf, which is laid on over the whole space intended to be covered by the figure; and is then imprinted with a hot brass

block, cut to the required design or letters. For this purpose a blocking-press is employed, and in the upper bed is a cavity containing a row of gas jets for keeping the block at the proper temperature. After the block has been brought down by means of a lever, the gold is readily brushed off from the parts which have not received the impression. Books bound in cloth are treated in the same manner, except that they do not receive the preliminary coating of *glaire*, the place of which is supplied by a portion of the glue under the cloth being raised by the heated block. The edges of the leaves of books are gilded in the bookbinder's press by applying a solution of isinglass or white of egg, moistened with oil, and then laying on the gold-leaf, which is firmly pressed down and burnished with agate, blood-stone, or polished steel. Instead of isinglass or ovalbumen, the serum of bullock's blood is often employed.

2. *Chemical Gilding*.—When metallic surfaces are to be gilded, the gold is applied either in the state of an amalgam, which is termed *wash-gilding*, or is deposited by chemical affinity from its solution.

Water or *Wash gilding* consists in applying evenly an amalgam of gold to the metallic surface to be gilt, and then dissipating the mercury by heat so as to leave on the surface a film of pure gold. Ordinary brass answers very well for gilding on, but the alloy which is now generally preferred is a mixture of copper, nickel, and zinc, which may be so proportioned as nearly to resemble gold in color. To form the amalgam, a small quantity of gold, reduced to grains or thin plates, is heated in a crucible till it becomes faintly red, and then thrown into mercury, also previously heated till it has begun to emit visible vapor. The proportion of mercury to gold is generally as six or eight to one. The mercury is then stirred with an iron rod till all the gold is dissolved. The crucible is now removed from the fire, and the amalgam, when cold, is squeezed in a bag of chamois leather, for the purpose of straining off the superfluous mercury. The true amalgam which remains consists of about thirty-three of gold and fifty-seven of mercury in a hundred parts; it is a yellowish silvery mass, of the consistence of butter.

Before applying the amalgam to the metallic surface, the latter is rubbed over with a solution, formed by dissolving a hundred parts of mercury in a hundred and ten parts, by weight, of nitric acid, of specific gravity 1.33, and diluted with about twenty-five times its weight of distilled water. This solution not only cleanses the metal from any rust or tarnish, but in consequence of the stronger affinity of the copper alloy for nitric acid than the mercury has, the latter is precipitated upon its surface in the same manner as a piece of polished iron precipitates copper from a solution of the sulphate of that metal. The amalgam is now spread evenly over the alloy to be gilt by means of a brush, and readily adheres to the metallic surface in consequence of the thin film of mercury already deposited upon it. Sometimes the metal is previously cleaned with sulphuric acid, and the nitrate solution and amalgam are then applied simultaneously. For this purpose a gilder's scratch-brush, made with fine brass-wire, is first dipped into the nitrate of mercury solution, and is then drawn over a lump of amalgam, placed on

the sloping side of an earthen vessel, after which the brush is applied to the surface of the alloy. This process is repeated till the whole is coated with its just proportion of gold. The article is then bathed in water, dried, and exposed to a fire of glowing charcoal to expel the mercury. The heat applied must be just sufficient for this purpose, and the article must be turned about to expose it equally on all sides. From time to time it is withdrawn from the fire, and while the operator holds it in his left hand, protected by a stuffed glove, he spreads the amalgam equally with his right hand by means of a long-haired brush. The piece is then returned to the fire, and the same operations are repeated till the mercury has entirely volatilized. This is known by the surface becoming of a dull yellow color, and by the hissing sound of a drop of water let fall upon it.

The surface, now coated with a film of gold, is still deficient in polish and lustre. To communicate these qualities, it is washed and well rubbed with a scratch-brush in water acidulated with vinegar. It is then covered with a composition called *gilding wax*, which is simply a mixture of bees' wax with some of the following substances, namely, red ochre, verdigris, copper scales, alum, vitriol, and borax. Coated with this composition, it is again exposed to the fire until the wax is burnt off. By this means the gilding is found to be heightened in color, probably in consequence of the complete dissipation of some of the mercury remaining after the former operations. If the article is wrought or chased, the parts intended to be burnished are now rubbed with a steel burnisher, dipped in acidulated water, till a fine metallic lustre is produced. Formerly hæmatite or bloodstone was almost exclusively used for this purpose, but is now generally abandoned for the use of the steel burnisher, which is case-hardened and then carefully polished. The parts intended to be deadened are coated with a mixture of sea-salt, nitre, and alum, fused in the water of crystallization of the last-mentioned salt; the article is then heated till the saline crust with which it is covered enters into fusion, and becomes homogeneous, after which it is withdrawn and suddenly plunged into cold water, which entirely detaches the crust. Lastly, the piece is passed through weak nitric acid, washed in pure water, and dried.

Gilding by immersion is another method by which copper trinkets and stamped articles can be coated with a thin film of gold. This method, which dispenses with the dangerous use of mercury, so detrimental to the health of the workmen, was patented by Mr. ELKINGTON, of Birmingham, in 1836, and has been very extensively practised, more especially in France. In this process the copper or other metallic articles to be gilt, are, after being well cleansed, immersed in a boiling-hot solution of terchloride of gold mixed with a solution of bicarbonate of potassa. The adhesion of the gold to the inferior metal takes place in consequence of a portion of the copper becoming dissolved by the action of the potassa, and the deposition of an equivalent of gold upon the copper article in its stead. The details and rationale of the process are thus described by Dr. MILLER of London:—The gilding-bath is prepared by dissolving one part of fine gold in aqua regia,

and expelling the excess of acid by evaporation. The chloride is dissolved in a small quantity of water. To this solution thirty parts of bicarbonate of potassa are gradually added. This liquid is then mixed with a solution of thirty parts more of the bicarbonate, dissolved in two hundred parts of water, and the liquid is boiled for two hours. During this operation the bicarbonate of potassa is converted into the sesquicarbonate, and the yellow liquid passes into green; after this, the solution is ready for use. The trinkets having been annealed, are cleansed from adhering oxide by a momentary immersion in a mixture of equal parts of sulphuric and nitric acids; to which, when the gold is intended to have a *dead* appearance, a little chloride of sodium is added. The articles are washed in water, and then plunged into the gilding liquid, where they are left for about half a minute, after which they are washed in water and dried in hot sawdust. This bath may be also employed for gilding on German silver, platinum, or silver, by immersing the objects composed of these metals in the liquid, in contact with wires of copper or of zinc. During this process of gilding, a remarkable reaction occurs—the gold imparts a portion of its chlorine to the excess of potassa contained in the bath, forming chlorate of potassa; protochloride of gold is formed, and is decomposed by the copper,—chloride of copper being produced, whilst metallic gold is deposited upon the surface of the trinkets:—

During this operation a black powder is precipitated, which contains hydrated carbonate of copper, mixed with a small proportion of the purple of Cassius derived from the action of the gilding solution upon the tin contained in the solder of the trinkets. The compound termed the purple of Cassius will be described afterwards.

Gilding on iron and steel cannot be well performed directly by the method of amalgamation, as it is difficult to prevent the oxidation of the metal during the volatilization of the mercury, and the temper of sword-blades, daggers, and other such instruments, to which the gilding is usually applied, is liable to be injured in the process. It may be effected, indeed, by previously applying to the polished surface the solution of nitrate of mercury already described, and known as *quicksilver water*; the acid so applied unites with a portion of the iron or steel, and deposits in its place a thin coating of mercury, which combines with the gold amalgam when brushed on. By this method, however, a bright and durable gilding cannot be obtained.

Another not very successful method of gilding on polished iron and steel, is by means of an ethereal solution of terchloride of gold. For this purpose the gold is first dissolved in aqua regia, and about twice the quantity of ether is then cautiously added in a large vessel. The liquids are agitated and allowed to rest, when the ether will separate, and float on the surface of the acid. The whole mixture is now poured into a funnel terminating in a small aperture, and again allowed to settle and separate, after which the acid is run off from below. The ether which remains has taken up all the

gold, and before applying it to the iron or steel, the metal is polished with the finest emery and spirit of wine. The ether is then laid on with a small brush, and as it evaporates it deposits the gold, which can now be heated and polished. This gilding, however, is neither very rich nor durable, in consequence of the affinity between gold and iron being feeble compared to that between gold and copper or silver.

But polished iron and steel, as well as copper, may be effectively gilded with gold-leaf by the application of heat. For this purpose, the metals are heated till the iron assumes a bluish tint, and till the copper has acquired a like temperature. The first coat of leaf-gold is then applied, being pressed gently down with a burnisher, and then exposed to a moderate heat. Several leaves, either single or double, are thus successively applied, and the last is burnished down cold. This is the method usually practised in gilding iron or steel.

Gilding on silver is performed by means of the ashes of a linen rag, which has been dipped in a solution of gold and copper in aqua regia. For this purpose, sixty grains of fine gold and twelve of rose copper are dissolved in two ounces of aqua regia. With this solution a quantity of linen rags sufficient to absorb all the liquid is soaked. The rags are then dried and burned, and the ashes contain the gold in powder. A moistened cork or piece of leather is dipped into this powder, and after the article to be gilt has been well annealed and polished, the ashes are rubbed over it with the cork till the surface appears sufficiently gilded. Large articles are finally burnished with bloodstone, and small ones with steel burnishers, along with soap-water.

Gilding on glass or porcelain is effected with pulverulent gold, or gold precipitated from its chloride solution by means of sulphate of iron. In this state the gold is mixed with one-twelfth of its weight of oxide of bismuth, together with a small quantity of borax and gum-water, and is applied to the parts to be gilt with a camel's hair pencil. The article is then heated in a muffle, and when removed the gold appears of a dingy color, but the lustre is brought out by burnishing with agate or bloodstone. Lastly, it is cleaned with vinegar or white-lead.

Vessels which are not often used, and are not liable to wear, may easily be gilt in a less durable manner, by fixing gold-leaf upon them with copal varnish.

3. *Electro-Gilding*.—This process, which has now almost entirely superseded the method by amalgamation, is applicable not only to metals, but to wood, plaster, or any other substance capable of receiving a coating of plumbago, or of PARKES' patent preparation of phosphorus. Full details of this beautiful process have been given in the article ELECTRO-METALLURGY, to which the reader is referred.

ARTIFICIAL GOLD.—Under the name of Californian gold, and other sounding titles, are sometimes sold alloys which do not contain one grain of the precious metal, but merely resemble it in color and lustre so long as they remain untarnished. It is stated that a good imitation has lately been formed by Messrs. MOURIER and VALLENT, of Paris. The materials and

proportions used by them are—pure copper, 100 parts by weight; zinc, 17; magnesia, 6; sal ammoniac, 3.60; quicklime, 1.80; tartar, 9. The copper is melted in a crucible, in a suitable furnace; the magnesia, sal ammoniac, lime, and tartar, are then added, separately and by degrees, in the form of powder; the whole is stirred for about thirty minutes to thoroughly mix the ingredients, and the zinc is then thrown on the surface, having first been ground into very small grains; the stirring is continued until the fusion is complete. The crucible is now covered, and the fusion continued for about thirty-five minutes, when it is uncovered and skimmed with care, and the contents are run into a mould of moist sand or metal. The material which results may be cast at such a temperature that any ornamental form may be given to it. It is very fine-grained, and is also damascene, malleable, and capable of taking a very brilliant polish. When tarnished by oxidation, its brilliancy can be restored by a little acidulated water. If tin be employed instead of zinc, the alloy will be still more brilliant.

COMPOUNDS OF GOLD.—Apart from the alloys of gold, the only chemical compounds of this metal possessing any importance, are the chlorides, the oxides, and a substance known as the *purple of Cassius*, of which the composition is still somewhat obscure.

Chlorides of Gold.—Gold forms two compounds with chlorine,—a protochloride, AuCl , and a terchloride, AuCl_3 . The latter is the most important chemical compound of the metal, and from it nearly all the other useful preparations of gold are made. It is prepared directly by dissolving gold in nitro-hydrochloric acid. On evaporating the solution, the terchloride may be obtained in ruby-red prismatic crystals, which are very fusible, and deliquesce on exposure to the air. It is very easily decomposed by heat, light, organic substances, and all deoxidizing or reducing agents. Hence the fingers or writing paper, if washed over with the solution, become stained of a violet color when exposed to the sun's light; and hence also its occasional use in photography. It is soluble in water, in alcohol, and in ether; and the latter solution, as already stated, is sometimes used for gilding steel. When heated to about 350° , the terchloride is transformed, by the expulsion of two-thirds of the chlorine, into a pale-yellow sparingly soluble powder, which is the *protochloride*. This is an unstable compound of no importance in the arts. At a red heat it loses its chlorine entirely, and metallic gold remains.

The terchloride is the usual and most convenient form of obtaining a solution of gold, and examining its properties in that state. The different reagents by which pulverulent gold may be precipitated from this solution, have been already mentioned. It is by this means that gold is obtained in a state of chemical purity.

Oxides of Gold.—The oxides of gold correspond to the chlorides, and are obtained from them,—the protoxide, AuO , from the protochloride, and the teroxide, AuO_3 , from the terchloride. The *protoxide* is obtained as a dark green powder by precipitating the protochloride by a dilute cold solution of potassa. It is permanent at ordinary temperatures, but a heat bordering

upon 480° decomposes it into metal and oxygen; kept in contact with a solution of potassa for some time, it alters to metallic gold and the teroxide. When digested with ammonia, it forms fulminating gold. The *teroxide* which possesses acid properties, and is therefore frequently termed *auric acid*, is the only well-known oxide of gold; it is usually prepared by digesting a solution of the terchloride of gold with pure magnesia, washing the precipitate with water, and removing the excess of magnesia by dilute nitric acid; but WAGNER recommends the following process:—Dissolve one part of gold in the usual way, render it quite neutral by evaporation, and re-dissolve in twelve parts of water; add to the solution one part of carbonate of potassa dissolved in twice its weight of water, and digest at about 170° . Carbonic acid gradually escapes, and the hydrated teroxide subsides, of a brownish-red color. After being well washed, it is dissolved in colorless nitric acid of specific gravity 1.4, and the solution decomposed by admixture with water. The hydrated teroxide is thus obtained nearly pure, and is rendered anhydrous by a temperature of 212° . In the state of hydrate it is yellow, but when anhydrous it is nearly black. It is insoluble in water, is very readily reduced by solar light, and at a temperature of about 470° it is resolved into metallic gold and free oxygen. It is quickly dissolved in hydrochloric acid, yielding the common solution of gold; but although it is likewise taken up by strong nitric and sulphuric acids, it forms no true salts or definite compounds with these or with any acids containing oxygen: so slight is the affinity, that the oxide is quickly precipitated by the addition of water. The hydrated teroxide, however, readily combines with the alkalies, apparently forming regular salts, which are termed *aurates*.

FIGUIER gives the following method in preference to the above, in consequence of its yielding a larger product, and at the same time a *purer oxide*. Dissolve one part of gold in four of aqua regia, and evaporate to dryness on the sand-bath at a gentle heat; wash the dry residue with water, till the undecomposed terchloride of gold is removed, and add a further quantity of aqua-regia to the residue, which consists of metallic gold and protochloride; after solution, evaporate and wash as before, and repeat the process till the whole of the metal is obtained as neutral terchloride. Add the various liquors together, and then an excess of potassa, till there is a strongly alkaline reaction manifested on testing with turmeric paper. The menstruum becomes turbid, but before the teroxide of gold precipitates to any appreciable extent, chloride of barium is added. This causes the deposition of a canary-colored aurate of baryta. When the precipitate begins to present a whitish aspect, the addition of the chloride of barium is discontinued; the aurate is washed by decantation till sulphuric acid fails to show that baryta is contained in the washings, after which it is acted upon by dilute nitric acid, with the view of dissolving out the baryta. To effect the latter completely, it is necessary to raise the temperature to ebullition. As in the previous case, the nitrate of baryta is removed by decanting the liquor, and the several succeeding washings, till an acid reaction ceases to be discerned with blue litmus paper.

In drying the precipitate, care is necessary, since at 212° it partly decomposes. FIGUIER recommends the pressing of the matter between folds of bibulous paper, and subsequently exposing it in a dark situation to air, till the last traces of moisture are eliminated.

Any gold which may be carried off in the washings of the aurate of baryta, described above, is recovered by adding to them sulphate of iron, after their concentration and the removal of the baryta with sulphuric acid.

The washings and solution from the separated teroxide of gold may likewise be operated upon in a similar way, only that it is necessary to remove the nitric acid before doing so. For this purpose, the liquid is evaporated, and the residue boiled for some time with an excess of hydrochloric acid till nitrous acid ceases to be evolved.

Fulminating gold may be prepared from recently precipitated teroxide, by keeping it in strong ammonia for about a day. A dark olive-brown compound is thus obtained. BERZELIUS assigns to it the composition $\text{Au O}_3 + 2 \text{NH}_3 + \text{HO}$, while DUMAS gives it as $\text{Au N} + \text{NH}_3 + 3 \text{HO}$. The Editor considers the former the more simple and probable view of its proximate composition, that is, regarding it as a diaurate of ammonia, and not a nitride of gold. A similar detonating compound is obtained when the terchloride is digested with an excess of ammonia; this is the ordinary mode of procuring fulminating gold. It subsides in the form of a yellow precipitate, the fulminating ingredient of which appears to be identical with that obtained from the teroxide. This compound may be dried at 212° ; but friction, or a heat suddenly raised to about 290° , produces a violent detonation. The best way is to dry it in the open air, and to make it only in small quantities at a time. Fulminating gold, however, has no application in the arts, in which respect it differs essentially from the following.

Purple of Cassius.—When a mixture of protochloride and bichloride of tin very much diluted, is added drop by drop to a dilute neutral solution of terchloride of gold, a flocculent purple deposit takes place, which has been termed *purple of Cassius*, from the circumstance that the method of preparing it was first described by ANDREAS CASSIUS of Leyden and his son, in 1685, under the name of *gold purple*. It may likewise be prepared by fusing together 150 parts of silver, 20 of gold, and 35.1 of tin, and acting on the alloy with nitric acid, which dissolves out the silver, and leaves a purple residue containing the tin and gold. To prevent the oxidation of the tin during the fusion, the three metals should be projected into a red-hot black-lead crucible, which contains a little melted borax. FUCHS states that the finest purple is produced by mixing a solution of sesquichloride of iron with aqueous protochloride of tin, till the yellow color is converted into pale green, and precipitating the gold solution with the mixture thus formed; he adds that the protochloride of iron in the liquid does not affect the product. This substance, in the moist state, is dark purple-red, and after drying, brown. Its true nature and composition have given rise to much discussion. According to some authorities, it contains metallic gold with hydrated stannic oxide;

according to others, the gold is oxidized. BERZELIUS concluded from the researches of M. FIGUIER, that it consists of a hydrated double stannate of gold and tin, as expressed by the formula,—

it is evident, as TURNER has remarked, both from the color of the compound, and its solubility in ammonia, that it is not a mechanical mixture of metallic gold and binoxide of tin, nor can it well be regarded as a chemical compound of these ingredients, since no definite combinations of that nature are known to chemists. The more probable supposition is, that it is a hydrated double salt, composed of binoxide of tin as the acid, united with protoxide of tin and binoxide of gold as bases, in such proportion that the oxygen of the gold exactly suffices to convert the protoxide into binoxide of tin. On this hypothesis, its composition would be expressed by the formula,—

Purple of Cassius is decomposed by the acids, but is not changed by the action of light. Hence it is somewhat extensively employed in the arts, chiefly for coloring glass and porcelain. When mixed with a little borax or some fusible glass, and applied to the surface of china, it imparts to it a beautiful rose or a rich purple color. Its different applications as a coloring material have already been explained in the articles ENAMELS and GLASS. It is remarkable that the oxide of tin does not appear to be essential, since even finely-divided metallic gold alone will give the same purple hue.

Burgos Lustre.—If finely-divided gold be heated with sulphur in contact with carbonate of potassa, a double sulphide of gold and potassium is formed, which resists a red heat, and is very soluble in water. This sulphur salt is likewise used for gilding porcelain, and produces the color known as *Burgos lustre*.

QUANTITATIVE ESTIMATION OF GOLD ORES AND ALLOYS.—In proceeding to determine the exact amount of gold present in an ore or alloy, it is obviously necessary to exercise the greatest caution in the sampling. Excellent advice on this point is given by Dr. PERCY in his admirable lecture on the metallurgical treatment and assaying of gold ores, delivered at the Museum of Practical Geology. Careless sampling, he remarks, can only mislead; assays of individual specimens may be accurate, but they are worse than useless if the assayer has not operated upon an *average* sample of the ore. He therefore advises the capitalist, to whom prospectuses of gold-mining schemes may be submitted, not to be allured with glittering specimens of gold ore, with assays yielding a high produce, and with the glowing statements of sanguine promoters or enthusiastic adventurers, without having ascertained on good evidence that the samples which are presented to his notice are really *average samples* of the ore, and that something like a continuous supply may reasonably be expected. If such specimens, he adds, do not represent an average, they become what the Cornish miner calls *stocking-stones*, which are at all times enticing and dangerous to the inexperienced and unwary, and never more

so than in the case of auriferous ores. The sampling generally devolves upon the miner, but the assayer and metallurgist should likewise understand the business. Assayers of great experience and high integrity may occasionally, he adds, commit unintentional mistakes. Thus, a few years ago, two small pigs of lead from South America, very rich in silver, were offered for sale. They were assayed by men of very high standing. Portions had been taken from the top and bottom of each pig, with a view to obtain a fair average. Dr. PERCY had occasion to attempt to verify the report of the assayers. Portions were taken from the same parts of each pig as in the first instance; but the results did not agree with the report, nor did Dr. PERCY's assays agree with each other on taking fresh portions. It was therefore certain that the composition was not uniform, and that the portions taken for the purpose of assaying in neither case represented an average. The pigs were accordingly sent again to the same assayers. Each pig was melted separately, and while melted a sample was taken. A second report was given, which differed from the former to the extent of one thousand ounces and upwards to the ton! In the sampling of gold ores most especial care should be taken, as the precious metal exists irregularly diffused through the mass, in particles of very different size, and as minute errors in sampling will necessarily be greatly multiplied when the quantity of gold per ton is calculated from the assaying of, it may be, five hundred or a thousand *grains* of ore.—*Percy*.

The quantitative estimation may be made, more or less correctly, by one of four methods: 1. By determining the specific gravity of the ore or alloy; 2. By the touchstone; 3. By chemical analysis, or the *wet method* of assaying; and 4. By the metallurgical, or *dry method*, in which fire is the principal agent. The first two afford only approximations, and the second is applicable only to alloys of gold; but both may be useful when circumstances render impossible or inconvenient the performance of an exact assay by the wet or dry method.

1. *Quantitative Estimation by Specific Gravity.*—It is evident that the high specific gravity of gold, in which it is exceeded only by platinum, not only affords facilities for separating it, by means of washing, from other matters, but also for estimating approximatively the amount in which it is present in any ore or mineral of known composition. The nature of the other ingredients being ascertained, and consequently their weight or specific gravity, the additional weight must be due to the presence of gold, and hence its amount may be calculated. Unfortunately, this quantitative test is rarely applicable to alloys, for experiment proves that an alloy composed of two metals has seldom a density corresponding to the mean which should be obtained by calculation from the relative amounts and specific gravities of its constituents. Thus, it has been found that alloys of gold with zinc, tin, bismuth, antimony, or cobalt, possess a greater specific gravity than the mean of the constituents, while alloys of the same metal with silver, iron, lead, copper, iridium, or nickel, have a specific gravity inferior to that of the mean. It will be seen that in the latter category are included the

metals most usually associated with gold, and hence it may be laid down as a general rule, that the specific gravity of *native gold*, containing an admixture of one or more of those metals, such as silver or copper, is *lower* than it ought to be theoretically. The following experiments by BOUSSINGAULT will show that a very remarkable discrepancy exists between the calculated and true specific gravity of a *native alloy* of gold and silver. In this case, three specimens of native gold were analysed, and their specific gravities, as found by experiment, are subjoined to the results obtained by a simple theoretical calculation:—

	First Specimen.	Second Specimen.	Third Specimen.
Gold,	88.24	73.45	64.93
Silver,	11.76	26.55	35.07
	100.00	100.00	100.00
Calculated specific gravity,	18.22	16.93	16.17
Actual,	14.70	12.66	14.14
Difference,	3.52	4.27	2.03

It is evident, therefore, that an estimate formed from the actual specific gravities of these native alloys of gold, as found by experiment, would have given too low a figure for the amount of gold present. *It is remarkable, however, that these alloys acquire a higher specific gravity after being melted.* Thus, the specific gravity of the first specimen rose, after fusion, to 18.10, or very nearly to what it ought to have been by calculation. Hence it may be assumed, that in artificial alloys, a nearer approximation would be obtained to the true value by this method than with native alloys. At the same time, when, as in the case of Australian gold, the metal is nearly pure, it is evident that the amount of it present in a piece of auriferous quartz, may be deduced with considerable accuracy from its specific gravity, and as the same method is calculated to afford a useful and convenient approximation even in estimating alloys, the *modus operandi* will be explained.

Fig. 231.

Taking for granted, therefore, that the mineral proposed to be submitted to this test is a piece of auriferous quartz—the first point to be determined is its specific

gravity, or its weight as compared with that of an equal bulk of distilled water; because, if this be no higher than that of common quartz, which is found by experiment to average 2.6, it will be unnecessary to proceed further; but if higher, the amount of gold present may be calculated from the difference or excess. Now, the specific gravity of a solid insoluble body, such as quartz, is very readily found by the hydrostatic balance, which in its simplest form is a common pair of scales, with a horse-hair or fine thread attached to the under surface of one of the scale pans. This balance, in its most improved form, is represented in Fig. 231. The substance of which the specific gravity is required is weighed in air, and then, being attached to the hair or thread, is immersed in distilled water at the temperature of 60° Fahr. and again weighed. The difference of the two weights will be that of its own bulk of water, and the specific gravity of the substance is the quotient of its weight in air divided by this difference. This method of ascertaining the specific gravity of irregular solids was one of the great discoveries of ARCHIMEDES, and may be thus explained:—When a body is plunged beneath the surface of a liquid, it obviously displaces a bulk of such liquid equal to itself, and, consequently, it is pressed upward or supported in the liquid with a force exactly equal to that with which the particles of the liquid were supported, when they previously occupied its place; the solid will therefore appear to have lost weight exactly equivalent to that of the bulk or volume of liquid which it occupies. Supposing, therefore, the weight of the auriferous quartz in air to be W , and its weight in water W' , the difference, $W - W'$, will represent the weight of an equal bulk of water, and if S be the specific gravity of the auriferous quartz, or mixture of rock and metal:—

$$S = \frac{W}{W - W'}$$

Having thus obtained the weight and specific gravity of the compound, and knowing the specific gravity of the constituents, it is easy to calculate the amount or weight of gold present. Or, assuming G to represent the weight of the gold, and g the specific gravity of that metal; R the weight of rock or quartz, and r its specific gravity; W the weight of the compound in air, and W' its weight in water, as before; then the weight of gold in the specimen may be found directly by the following formula:—

$$G = \frac{g [W - r (W - W')]}{g - r};$$

and the weight of pure quartz, if required, by this formula:—

$$R = \frac{r [g (W - W') - W]}{g - r}.$$

When the gold ore is in the state of powder or small grains, a somewhat different process must be employed to obtain the weight of a volume of water equal to that of the mineral under examination. In this case, the instrument called the specific gravity bottle, and repre-

sented in Fig. 232, is most conveniently employed. It usually consists of a cylindrical bottle, which may be

Fig. 232.

graduated or not, and the stopper of which, nicely fitted by grinding, is so adjusted that it cannot sink beyond a line marked upon the neck of the phial. When the latter is filled with distilled water, and the stopper inserted, the superfluous liquid escapes by a capillary tube which is formed in the stopper for that purpose, as shown in the figure, and thus the bottle is exactly filled, and all air is expelled. Such bottles are usually made to contain precisely one thousand grains of distilled water at the temperature of 60°, so that when once filled with water at that temperature, the weight of the included liquid is known.

To ascertain the specific gravity of an insoluble powder by this instrument, the powder is first weighed in the air by means of a delicate balance, and its weight noted. It is then introduced into the bottle of distilled water, from which, when the stopper is inserted, a portion of liquid will escape, precisely equal in volume to that of the mineral introduced. The bottle, containing the water and mineral, is now carefully wiped dry, and weighed—a counterpoise equal to the known weight of the bottle having been previously placed in one of the scales. The weight found will evidently be that of the whole water and mineral together, *minus* the weight of a volume of water equal to that of the mineral. If, therefore, *M* be assumed to represent the weight of the mineral in air, *W* the weight of water which exactly fills the bottle, and *W'* the weight of water and mineral in the bottle, it is evident that *M + W - W'* represents the weight of water which has been displaced by the mineral, or in other words, the weight of a volume of water equal to its own bulk. Hence the specific gravity, *S*, of the mineral, or its weight in air, in terms of an equal bulk of distilled water as unity, is found by this formula:—

$$S = \frac{M}{M + W - W'}$$

Suppose, for example, that the substance to be examined resembles gold dust, and that it is found to weigh in air 150 grains. Let the bottle be assumed to contain exactly 1000 grains of distilled water, and when a portion of this is displaced by introducing the heavier mineral, let the weight of the contents of the phial be 1140 grains. In this case, *M* = 150, *W* = 1000, and *W'* = 1140. Hence, *M + W - W'* = 10; and, consequently, by the preceding formula:—

$$S = \frac{150}{10} = 15$$

instead of 19.5, the specific gravity of pure gold; from which it may be inferred that a considerable amount of the precious metal is present, though very far from being in a state of purity. The absolute amount of gold can only be estimated, provided the nature of the substances with which it is associated is known.

The trouble of weighing the contents of the bottle

may be entirely avoided, and thus the operation simplified, by employing a modification of the same vessel provided with a narrow neck graduated to grains of distilled water, which will show at once the amount of liquid displaced. A phial of sufficient capacity to contain not more than from 150 to 200 grains of water, will generally be most convenient for this purpose.

2. *Quantitative Estimation by the Touchstone.*—Another method of estimating approximatively the amount of gold, not in auriferous ores, but in native gold or artificial alloys, is by the use of the touchstone—a method which may be practised with considerable advantage, when the apparatus and reagents necessary for the carrying out of a complete assay cannot be conveniently procured. It is more especially applicable to the estimation of trinkets or other finished articles, which could not be submitted to the assaying processes, either by the wet or dry method, without destroying them.

The touchstone test essentially consists in rubbing some convenient part of the object to be examined on a smooth piece of black basalt or pottery, which for this reason is termed the *touchstone*, and comparing the marks so formed with those produced by one or other of a series of small bars or needles, consisting of alloys of gold with silver or copper in known proportions. The material commonly employed as the touchstone, and generally known by that name, is a species of quartz, colored dark by bituminous matter, and of which large quantities are found in Saxony, Bohemia, and various other localities. Black flint slate will serve the same purpose. The sets of needles or bars may vary from pure gold, through a well-graduated proportion, to equal parts of gold and silver, equal parts of gold and copper, or various mixtures of all three metals in determinate quantities. The fineness of each bar is marked in carats—a mode of valuation which has been already explained.

In proceeding to make an assay by this method, the first streak obtained by rubbing the object to be examined on the touchstone cannot be safely employed to ascertain its composition, if it be a manufactured article, because, by a process previously described, the surface of jewellery is invariably rendered of a higher standard than that of the mass. The object must therefore be passed once or twice over the back or edge of the stone, in order to remove the superficial film of richer metal, before making the streak from which its quality is to be judged. Other streaks are then made successively with two or three of the needles which the assayer, guided by experience, considers to approach nearest in composition to the article under examination. In doing so, he compares not only the color of the streaks made upon the touchstone, but likewise the sensation of roughness, dryness, smoothness, or greasiness which the texture of the rubbed metals excites when abraded by the stone. When he succeeds in obtaining with one of his needles a streak which is perfectly similar in appearance to that produced by the article which forms the subject of experiment, he then moistens both streaks with nitric acid, which will affect them differently if they be not similar compositions. That which has the least gold will be

most affected; on the contrary, if the gold be pure, the streak will remain unaltered. If the actions do not correspond, his experience will enable him to judge in what they differ, and will direct him in selecting another needle to submit to the same comparative test. When one has been found which agrees satisfactorily in all particulars with the metal submitted to examination, the latter is assumed to possess a similar standard of fineness to that which is indicated by the mark on this particular needle.

Nitric acid of specific gravity 1.20 is commonly employed in this operation, with sometimes an addition of about two per cent. of hydrochloric acid. Although the results obtained cannot be relied on where absolute accuracy is required, yet they afford a useful approximation, not only in estimating the value of manufactured articles which cannot be submitted to a regular assaying process, but also in obtaining that preliminary knowledge of the general composition of an alloy, which is so important to the assayer in proceeding to a detailed analysis. The touchstone is therefore of great use in practised hands, but it is of little avail in the hands of an inexperienced operator.

3. Quantitative Estimation by the Wet Method—Analysis.—However useful the approximations obtained from the specific gravity of an auriferous ore, or the application of the touchstone to an alloy of gold, it is evident that more exact methods are required to determine with absolute precision the value of an alloy or ore of this precious metal. Accordingly, there are two methods by which the assaying of gold ores or alloys may be conducted with perfect accuracy, and these are distinguished as the *wet* or *dry* method, according as the agency of liquid solvents or that of fluxes and fire is employed. For practical purposes, in the determination of gold, the latter process is always adopted, although in the final separation of the silver even the dry method, as now practised, involves the application of a liquid solvent.

The principles of the quantitative estimation of gold by the humid method have been already explained in detailing the laboratory process for the preparation of pure gold, and in describing the application of the tests or reagents by which its presence is detected. It is evident that any of the qualitative tests which result in precipitating the gold from its solution in aqua regia, such as protosulphate of iron, may be converted into the means of obtaining a quantitative estimation, by simply weighing the amount of ore or alloy on which the experiment is performed, and then weighing the amount of pure gold, carefully washed and dried, which is obtained in the form of a precipitate. It will therefore be unnecessary to enter into minute details on the chemical principles involved.

It may be stated, however, that if the substance to be examined be a natural or artificial alloy, composed chiefly of the pure metal, such as the gold dust of California or Australia, the quantity taken for the analysis should not exceed fifteen grains. A convenient quantity is twelve and a half grains, as it is then only necessary to multiply the result by eight to obtain the per-centage composition. In performing analyses very small quantities are taken, because it is

easier to operate upon a few grains than upon a large mass; the effect of the reactions is more rapid; there is less waste of materials; and as accurate results can be obtained with a small as with a large quantity, provided sufficient precaution be taken to operate upon an average sample. If the gold be mixed with earthy or quartzose matter, so much of this should be taken as may be judged, from preliminary experiments or other sources of information, to contain the amount of native gold above-mentioned; and this must be triturated in a mortar with great care before subjecting it to the action of the aqua regia—a precaution of less importance in merely testing for gold, but absolutely necessary and essential when it is required to ascertain the exact amount of the precious metal present; for, unless the quartz be reduced to a state of the most minute division, it is evident that much of the gold remaining enveloped in the quartz will escape the action of the acid.

Whatever the precise amount taken, the ore or alloy to be examined must be weighed with extreme accuracy, and then introduced into a Florence flask or any other convenient glass vessel for boiling liquids. Supposing the compound to contain from twelve to fifteen grains of native gold, about an ounce of aqua regia is now poured upon it; the flask is then placed on a retort-stand or sand-bath, and the mixture is allowed to digest at a moderate heat for about half an hour. At the end of that time the gold will be completely dissolved, and the silver, if any be present, will be found in the form of an insoluble chloride, mixed with the silica at the bottom. The heat may then be increased under the flask, and the solution boiled off until it is diminished to about an eighth or tenth of its original quantity. At the same time a little hydrochloric acid should be added occasionally for the purpose of expelling or decomposing the nitric acid, the presence of which is injurious in the after part of the process. The addition of a little carbonate of soda will serve the same purpose. The reader will recollect that the function of the nitric acid is merely to liberate the chlorine, which is the real solvent of gold.

When the evaporation has been carried sufficiently far, three or four ounces of water should be added, after which the contents of the flask must be allowed to remain in perfect rest until the undissolved matter has completely subsided, and the supernatant fluid is quite clear. The latter is then to be carefully decanted or filtered off, and to the residue about an ounce of fresh water must be added, left to stand till clear, again decanted or filtered; and this operation repeated five or six times, always adding the later washings to the first portion of fluid. The solution of gold now obtained will be very dilute. Add to it, therefore, a few drops of hydrochloric acid, and then introduce the protosulphate of iron, which, when the liquid is well stirred, will speedily precipitate the whole of the gold in the form of a brown powder. If oxalic acid be used for the same purpose, the liquid ought to be boiled. When the whole of the precipitate appears to have settled to the bottom, a few drops of the clear supernatant liquid should be taken out on the end of a rod, placed upon a surface of clean white porcelain, and

tested with a drop of the solution of protochloride of tin. If no purple precipitate be formed, it is a proof that the whole of the gold has been thrown down. If a dark brown coloring, but still no subsidence, be produced, this will indicate the presence of platinum. If any precipitate be observed, more of the sulphate of iron or oxalic acid must be added to effect a complete precipitation of the gold contained in the solution.

When the pulverulent gold has entirely deposited, the liquid must be decanted or filtered off with the greatest precaution. Care must be taken that not the smallest particle of the gold powder is allowed to pass away with the liquid. A little hydrochloric acid, which must be quite free from any admixture of nitric acid, is then to be poured upon the precipitate. This will remove any iron or other metallic impurities without dissolving the gold. The latter is then to be washed, at least six times, with successive portions of distilled water; and lastly, it is transferred to a small porcelain or platinum crucible, in which it is heated over a spirit lamp, till the last portions of water are expelled. It ought, in fact, to be raised to a red heat, or even to be fused with a small quantity of borax and nitrate of soda, as formerly recommended, to expel the last traces of chloride of silver.

The pure gold thus obtained is then to be placed in a watch-glass or small capsule, and accurately weighed in a pair of delicate scales, which should be capable of turning with a difference of at least one-hundredth part of a grain. Instead of first counterpoising the dish or capsule, and then adding weights to counterpoise the gold, it is better to begin by placing the capsule *containing the gold* in one pan, and counterpoising both by means of sand, or some other convenient material placed in the other. The gold is then removed from the dish, and weights put in its stead sufficient to restore the equilibrium. The number of grains and fractions of a grain required for this purpose will accurately represent the weight of the gold; and in this method of *weighing by substitution*, as it is termed, any risk of error arising from the possible inequality in length of the two arms of the balance will be entirely avoided.

Supposing the gold to weigh exactly 10·75 grains, and that the amount of alloy submitted to experiment was 12·5 grains, or the eighth part of one hundred, it is evident that $10\cdot75 \times 8 = 86$ is the per-centage of pure gold present.

4. *Quantitative Estimation by the Dry Method—Assaying.*—The fourth and last method of estimating the amount of gold in an ore or alloy, is by the use of fluxes and fire. It is therefore termed the *dry method*, and formerly even the separation of the silver was effected without a liquid solvent, by one or other of the dry processes described in connection with the operation of parting on the large scale; but now the agency of an acid solution is employed in the last part of the process.

This metallurgical method, to which the name of *assaying* is strictly confined, when not otherwise expressed, is that uniformly practised at the Mint, and other regular assaying establishments, being not only more expeditious than the wet method, but admitting

of a greater number of assays being conducted simultaneously. The wet method is useful for special or occasional assays in the laboratory, where assaying furnaces, cupels, *et cetera*, cannot be kept constantly in requisition. On the other hand, the dry method is the best where assaying is practised as a business, and where all the apparatus required is therefore in constant efficiency. This method consists in the following processes: 1. Fusion, to separate earthy and other gross impurities, which may be either performed in a crucible by means of oxide of lead, or by the method of *scorification* with metallic lead. 2. Cupellation, to remove the copper and other base metals by oxidation and absorption. 3. Parting by inquantation, or separation of the silver from the gold, by dissolving the former metal in nitric acid.

From this enumeration of the different operations which constitute the process of assaying by the dry method, it will be seen that this process is nothing more than a miniature representation of the smelting and refining operations already described. It will therefore be unnecessary to explain the principles on which this important department of the subject is founded, as those already enunciated in reference to the smelting and refining of gold ores, apply equally to the assaying of these ores, as well as of artificial alloys. The principal difference between the two cases consists in the fact, that the assayer operates upon a few grains instead of large quantities, while, at the same time, he must exercise the utmost precaution in attending to the weight and proportions of his materials.

Fusion with Oxide of Lead.—Assuming, as before, that the ore to be assayed is gold quartz, it must first, as in all other cases, be reduced to a fine powder, by triturating in an iron mortar. This operation is much facilitated by heating the quartz to redness, and plunging it in cold water. Having pulverized a few thousand grains, it is usual to make at least two assays of the sample, to test the correctness of the result. For each of these weigh five hundred or a thousand grains, according to the richness of the ore, and mix intimately on a clean surface of glass, or highly-glazed writing paper, with about the same weight of litharge or red lead, half the weight of dry carbonate of soda, and five per cent. of finely-powdered charcoal. The precise quantities are not very important; but it is better that the carbonate of soda should be in excess, than that it should fall short of the above proportion. This mixture is introduced into a Cornish or black-lead crucible, of which it should not fill more than two-thirds the capacity; it may then be covered with a thin layer of borax, and is afterwards fixed solidly in the assay-furnace, by surrounding it with fuel.

Furnaces proper for assaying are of several different kinds, and the required temperature may be obtained in them either by supplying an artificial blast of air by some blowing apparatus, or by connecting the furnace with a chimney sufficiently high to establish a strong natural draught. When the materials for its erection can be obtained, the ordinary wind-furnace is to be preferred. This is represented and fully described, in connection with the assaying of copper ores, at page 498, vol. I., to which the reader is referred. For the

travelling assayer, however, a portable apparatus is required, and in this respect SELFSTRÖM'S blast-furnace offers peculiar advantages. This consists of two cylinders of sheet-iron, placed one within the other, as represented in the annexed drawing, Fig. 233. A represents the outer cylinder, which answers the purpose perfectly well when not larger than a man's hat; and B the inner one, lined with a coating of fire-clay about an inch in thickness. Both cylinders are provided with a bottom, and are fixed together at the top, air-tight, by a horizontal hoop or flat ring of metal, E E, in such a way as to leave an equal space, C C, between their sides and bottoms. The interior cylinder, B B, is pierced at about the middle of its depth with eight holes, D D, which pass through the lining of fire-clay, and all point to the centre of the furnace, where the crucible, H, is placed on a piece of fire-brick, kept in

Fig. 233.

its position by a little fire-clay, and surrounded with fuel. For a small furnace of this kind charcoal must be employed as fuel, and should be broken into pieces about as large as a walnut. The air is blown into the opening, F, by means of a double-action bellows; or a simple rotating fan, like that employed for domestic fires, may be used. By this means the air is compressed into the space C, where it is partially heated, and is thence driven in a steady equable current through the holes D D, into the cavity of the furnace. The heat which may thus be produced with a furnace having an internal diameter of not more than six inches, is so intense as to be capable of melting manganese, or several ounces of cast-iron, with the greatest ease.

To proceed with the fusion. It has been stated that the mixture above-mentioned, when introduced into the crucible, should not fill more than two-thirds of its capacity. This precaution is necessary on account of the effervescence which will take place, owing to the displacement of the carbonic acid from the carbonate of soda by the silica, and the combination of the carbon with the oxygen of the litharge. The heat is continued till perfect fusion is effected, and towards the last the temperature is raised to bright redness, until no further effervescence occurs, and a clear liquid homogeneous slag is obtained. The crucible must then be immediately removed from the fire, otherwise the

unreduced litharge would be liable to cut through the pot; and as dexterously and rapidly as possible, the slag, which constitutes the upper portion of the contents, is poured into one of the two hemispherical cavities of a cast-iron ingot-mould, Fig. 234, and then the lead, with adhering slag, into the other. If any particles of lead are found attached to the slag which is poured into the first cavity, they must be carefully separated by trituration and washing, and added to the button of lead in the other cavity. The latter is then taken out, and struck carefully on the side, on a bright anvil, with a hammer, to detach any portions of slag that may still adhere to it. Sometimes the crucible is broken to extract the button of lead, but this may be avoided by the method above described, if executed with sufficient dexterity. The whole of the gold, with any silver that may be present, remains in the lead, which is then subjected to the process of cupellation.

Fig. 234.

The proportion of oxide of lead to be used in the fusion will necessarily vary with the amount of oxidisable substances present; but this compound should in all cases be added in excess, since, if the slags retain any traces of an alkaline sulphide, these will retain a part of the gold. PHILLIPS states that for the assay of iron pyrites about thirty parts of oxide of lead are necessary, whilst for mispickel, zinc blende, copper pyrites, grey cobalt, and sulphide of antimony, from fifteen to twenty-five times their weight only may be employed. When auriferous pyrites is the subject of examination, it must first be reduced to fine powder, and then roasted in a shallow dish of refractory clay, heated to low redness in a large muffle, until the odor of burning sulphur ceases to be evolved. As the sulphur burns away, the temperature is gradually raised to bright redness. The pyrites is thus converted into oxide of iron. Of this product one thousand grains or more may be taken, and mixed with five hundred of dry carbonate of soda, three hundred to five hundred of litharge or red lead, with five per cent. of charcoal, or the same quantity of granulated metallic lead without charcoal, and lastly, about five hundred of dried borax. This mixture is heated, introduced into the crucible, and fused as for quartz or other common ores. The fuel should be either charcoal, coke, or anthracite. For small portable furnaces, such as SELFSTRÖM'S, charcoal is employed, but anthracite is found to be well adapted for the air-furnace, and is characterised by the power of producing an intense heat in a short time, over a space confined to a few inches above the bars.

The principal objection to this method of assay is the large amount of lead which is produced for cupellation, since pure iron pyrites affords, when thus treated, eight and a half parts of lead, whilst sulphate of antimony and grey copper ore yield from six to seven parts. This inconvenience, as well as the trouble of roasting, may be avoided by the cautious and gradual addition of nitrate of potassa, which effects the partial oxidation of the mineral, and enables the skilful assayer to pro-

cure a metallic button of almost any required weight. The nitre, however, if employed in excess, would determine the oxidation of all the metallic and combustible substances contained in the mineral, except the gold alone, which is never present in sufficient quantity to form a button. The exact amount of nitre to be added must depend on the nature and richness of the ore. As a general rule, it may be stated that two and a half parts of nitre are sufficient to completely oxidise one part of iron pyrites, and that one and a half and two-thirds their weight, in the case of sulphide of antimony and galena, are sufficient to produce the same effect on these ores.

Alloys of gold containing *tin* and *zinc* must likewise be fused, before cupellation, with nitrate of potassa, to oxidise these metals; and by adding about sixteen parts of lead, when the mixture is quite melted, they are separated in the state of slag or scoria, leaving, as before, a button of lead containing the whole of the gold, which is now ready for being cupelled. But before describing this part of the assaying process, the method by scorification, which is often preferred to that of fusion with oxide of lead, will be briefly explained.

Method by Scorification.—Scorification, or, in other words, the conversion of the silica and other impurities into a scoria, is simply another method of fusion, in which, however, metallic lead, instead of its oxides, is employed; and the oxidation of the various substances to be removed is produced by the aid of atmospheric air, whilst the litharge necessary for the fusion of the earthy and silicious matters is formed by the oxidation of a portion of the metallic lead. For this operation, instead of a crucible, a shallow cup-like vessel, termed a *scorifier*, is employed. This vessel, the form of which

Fig. 235.

is represented in Fig. 235, should be made of refractory clay, and be as compact in structure as possible, in order to resist the corrosive action of melted litharge. The scorifier with its contents is heated in the muffle of an ordinary assay-furnace, and as many assays may be introduced at one time as there is room for in the muffle.

A very convenient furnace for this purpose, as well as for the subsequent process of cupellation, is shown in elevation and vertical section in Figs. 236 and 237, and the form of the muffle is represented in Fig. 238. This last apparatus is a small arched vessel of fire-clay, closed at one end, and furnished with small holes or perpendicular slits in the sides and closed extremity, to allow of the free circulation of air through the interior. It is introduced by the opening, A, into the furnace, which is made of sheet-iron lined with fire-clay; and when adjusted in its place—as shown in Fig. 237—it is supported at one end by a shelf at the back of the furnace, while the other or open extremity exactly fits the opening, A, to the sides of which it is carefully luted by a little moistened fire-clay. In this position it is surrounded with ignited fuel, by which it is equally and readily heated on all sides; while the openings in its end and sides admit of the passage of a current of air into its interior, and the draught is kept

up by the addition of a long chimney or funnel, F, so that the muffle is constantly traversed by a highly oxidising current. The ledge around the chimney is

Fig. 236.

Fig. 237.

intended for drying the scorifiers or cupels before introducing them into the muffle. In lighting the furnace, a little ignited charcoal is first introduced by the opening, C, and the body of the furnace above and below

Fig. 238.

the muffle is afterwards well charged with the same fuel, or with good hard coke broken into small pieces. The whole of the openings are then closed by means of their slides or lids, with the exception of the ashpit, D, which is left open to supply the requisite draught.

Before introducing the ore into the scorifiers, it is reduced to powder, and a determined weight of it is intimately mixed with several times its weight of finely-granulated lead, free from silver. The scorifiers charged with this mixture are then placed in the muffle, and the door at the mouth being closed, they are strongly heated in the muffle during a quarter of an hour. By this time the lead will be completely melted, and the mouth of the muffle is again opened. The scorifying process now proceeds in consequence of the current of heated air which passes through the muffle; in other words, the lead is oxidised, and the foreign metals present, whether in combination

with sulphur or oxygen, are attacked and dissolved in the litharge in proportion as this oxide is formed. At first the slags are frequently solid, but gradually become soft, and more and more liquid in proportion as the quantity of oxide of lead increases. Towards the conclusion of the operation, the muffle is for a short time strongly heated to render the slag or scoria completely liquid. When a small iron rod, previously heated to redness and then placed in the mixture, is found, on being withdrawn, covered with a slight film of scoria which runs clean off, the scorification is known to be sufficiently advanced. The scorifiers are then successively withdrawn from the muffle by means of tongs, and the contents are rapidly poured into a circular ingot-mould of the form represented in Fig. 234. When cold, the adherent litharge is detached from the button of lead by a few blows with a hammer. This button contains all the gold and silver which may have been present in the ore, and which are subsequently separated from the lead by cupellation.

If the ore is poor, the whole of the precious metals contained in a large quantity may be concentrated in one small button of lead, by repeating the process on a fresh portion of ore mixed with a suitable quantity of lead, and introducing into this assay the button first obtained. A second button of the same weight as the first, and containing all the precious metals from the two quantities of ore, will thus be procured. The same process may be repeated a third, fourth, or any number of times, till the button of lead last obtained becomes as rich in the precious metals as may be required. It is necessary, however, that a certain amount of lead should be present, with a view to the next process, that of cupellation. In many cases so much as eight times the weight of the ore is employed, but the button may be reduced by a single operation to one-sixth or even to one-eighth of the original lead. Indeed, it is the highest recommendation of this process, as compared with the method by fusion with litharge, that however small may be the proportion of lead, the slags produced never contain any oxy-sulphides at the close of the operation, and, therefore, they seldom retain the slightest trace of either gold or silver. The process of scorification has therefore been justly characterized as one of the most exact methods that can be employed—simple, effective, and applicable to the assay of all kinds of auriferous and argentiferous ores, without exception.

Cupellation of the Assay.—The process of cupellation on the large scale has been already described. When applied to assays the principle is the same; but in this case the whole of the melted litharge and other oxidised matters are removed by absorption into the cupel; whereas it has been shown that, in operating on large quantities, the cupel is soon saturated, and the greater part of the litharge and other oxides are allowed to run away, or are expelled by the current of air which exerts the oxidising action.

The cupels for assaying purposes are formed of the same material as those employed for refining on the large scale, and described at page 284; but they are necessarily much smaller, and are considerably simpler in the manufacture. They are made by pressing the

moistened bone-earth into a mould, which consists of a short, stout cylinder, A—Fig. 239—either of cast-iron or gun-metal, open at both ends, and having the diameter of the cavity somewhat greater at the top than the bottom. Its usual dimensions are as follow:—Interior diameter at top, one and nine-sixteenths of an inch; interior diameter at bottom, one inch and a half; depth, two inches. To make a cupel, the cavity is nearly filled with bone-ash, which is first compressed slightly with the hands, and afterwards by means of the plunger, B, which is formed of the same metal as the mould, and has the lower end turned convex, so as exactly to correspond to the concave surface of the cupel. When the plunger is introduced, it is struck several times with a mallet till the bone-ash is well consolidated. The plunger is then withdrawn, and by inserting at the lower and smaller end of the mould a solid wooden cylinder, which exactly fits the aperture, the cupel is readily forced out, and is then placed to dry on the ledge which surrounds the furnace chimney—Figs. 236 and 237. The diameter of the cupel—Figs. 240 and 241—is about one inch and a half, and its cup-like cavity is very shallow, being not more than three-fourths of an inch deep.

Cupellation, like the process last described, is performed by means of a muffle, Fig. 238. When the muffle has become red-hot, six or eight cupels are successively introduced into it, by a pair of light tongs of the form represented in Fig. 242; and to prevent the

Fig. 239.

Fig. 240.

Fig. 241.

Fig. 242.

floor of the muffle being corroded should any of the oxide of lead be spilt on it, it is previously covered with a thin layer of pounded bone-ash. In the furnace of the Mint, the number of assays that can be made at one time is forty-five, and the same number of cupels are put into the muffle. When the cupels are introduced, the door of the opening into the muffle is closed for a few moments, while the draught-hole of the furnace is kept open till the cupels are raised to the temperature of the muffle itself. The slide is then withdrawn, and into each of the cupels is introduced, by a pair of slender tongs, a button of the alloy to be assayed.

By the previous process of fusion with litharge, or that of scorification, if deemed preferable, the earthy impurities have been removed in the form of slag or scoriae, and nothing now remains but the gold, or a mixture of gold and silver, in combination with the lead and any other metals that may be present. The process of cupellation, as previously stated, consists in the oxidation of the lead and other oxidizable metals, and their absorption by the cupel. It is, in fact, a condition essential to the success of the assaying pro-

cess that the whole of the oxides should be imbibed, and thus removed. But the power of absorption in a cupel varies according to its texture, and the care with which the material has been prepared. On an average, it may be calculated that it will absorb about its own weight of fused litharge. This, though not strictly correct, will afford a general guide to the experimenter, as regards the amount of lead which ought to be mixed with the assay. It is evident, on the one hand, that this must not exceed the absorptive power of the cupel. On the other hand, the actual amount, within this limit, must depend on the nature of the compound or alloy upon which the cupellation is to be performed; but supposing that the subject of assay is an alloy of gold and copper, the following table will give the quantity of lead required for the separation of the copper. In treating an alloy of gold and silver with copper, the quantity of lead may be somewhat diminished; but, in cupelling an alloy of copper with gold alone, a small excess of lead is not injurious, as, in consequence of the gold not being volatile, like silver, the heat can be raised and sustained for any required length of time, so as to oxidize the last portions of lead. In this table, which is adapted by Mr. T. W. KEATES, from one given by BERTHIER for the assay of silver—the proportion of lead being altered to render it applicable to the cupellation of gold—the first two columns express respectively the quantities of gold and of copper, and the third column the parts of lead by weight required for one part of the alloy, according to its composition:—

Alloy.		
Quantity of gold.	Quantity of copper.	Proportion of lead required.
1000	0	3-10lbs
950	50	6
900	100	14
800	200	20
700	300	24
600	400	28
500	500	32 to 35
400	600	32 to 35
300	700	32 to 35
200	800	32 to 35
100	900	32 to 35
0	1000	32 to 35

It must be observed that the numbers in the third column indicate multiples of one part of the alloy. It may appear surprising that, at and below the point at which the alloy contains equal parts of gold and copper, the same proportion of lead is required, whatever may be the proportion of the copper. This fact, however, has been fully verified by experience. It requires, in short, as much lead to remove the copper from an alloy of equal parts of that metal and gold as it would to carry off a quantity of copper equal to the weight of the copper and gold together. It may be added, that when the assayer has reason to know pretty nearly the composition of the alloy, it is well to insure the presence of at least two or three times more silver than gold, which is not only useful in the cupellation, to guard against loss of gold, but is necessary, as already stated, for the subsequent operation of parting.

The assays being placed in the cupels, the door is a second time closed during a few minutes, to facili-

tate the fusion of the alloy; and on opening it again, each of the cupels is found to contain a bright convex metallic globule, in which state the assay is said to be *uncovered*. The air is now freely admitted, and rapidly converts the lead into litharge, which, as fast as it is produced, is absorbed by the bone-ash of the cupel. While this operation is going forward, the rounded surface of the liquid button appears to be covered with bright patches and lines of color; these are produced by the thin film of oxide of lead which is constantly forming, and passing off from the centre to the edges of the assay, where it meets with and sinks into the porous matter of the cupel, leaving always a new surface exposed to the current of air which is carried by the draught through the muffle. At the same time there rises, and passes through the openings of the muffle, a white vapor, which is caused by the volatilization and combustion of a portion of lead. When this vapor is very thin, and rises with great rapidity, it is an indication that the heat is too great, and part of the draught must be stopped; on the other hand, when it is thick and heavy, and hangs sluggishly over and around the cupel, the temperature is too low, and the power of the draught must be increased.

As soon as the greater part of the lead has been thus converted into litharge and absorbed, the remaining bead of rich alloy appears to become agitated by a rapid circular movement, and the bands of color with which the surface is covered arise and vanish in quick succession. This is a sign that the process is on the point of completion, and means must now be taken to increase the heat of the furnace for a short time, so as to insure the expulsion of the last remaining portions of lead. But if silver be present in the assay, and if it be desired to estimate also the amount of that metal, the increase of temperature towards the end of the process must be of short duration, otherwise a portion of the silver would soon volatilize. Immediately before the conclusion of the process, the assay becomes somewhat dull, and the movements on its surface can no longer be observed; but after a few moments, it again suddenly lights up with a kind of flash or coruscation, and then becomes permanently brilliant and immovable, —assuming, in short, the fixed metallic lustre of pure melted gold or silver. If the cupellation has been well performed, the gold, or the mixture of the two precious metals, is now in a state of almost chemical purity.

When the phenomenon termed the *flashing*, *brightening*, or *coruscation* of the assay indicates that the cupellation is terminated, the mouth of the muffle ought to be closed for thirty or forty seconds, and then the cupel containing the button of pure metal may be drawn to the front of the muffle, and allowed to cool slowly. The refrigeration must not be too rapid, otherwise there may be very sensible loss by *spitting*, *sprouting*, or *vegetation*—an effect, however, only produced when a large proportion of silver is present, and which has been already explained in connection with the process of cupellation on the large scale. To insure gradual cooling, it is occasionally convenient to invert over the cupel containing the bead another heated cupel.

The button is detached from the cupel after cooling

by a pair of fine steel forceps, and gently squeezed between the jaws of a pair of pliers, to loosen and pulverize any adhering litharge, which is finally cleaned off with a small brush made of brass wire or stout bristles. If the process has succeeded, the button should be round and bright upon its upper surface, but somewhat rough or crystalline on the part by which it was attached to the cupel, from which it ought to be capable of being removed without difficulty.

Even after cupellation, there always remains a trifling admixture of copper in the assay, which is called the *surcharge*, unless there has been present a sufficient proportion of silver. This metal greatly facilitates the separation of the copper, and when it is present in the proportion of three parts of silver to one of gold, the copper can be completely separated. This is one important reason for adding the requisite amount of silver before cupellation. But although silver is not appreciably oxidised or volatilized when melted alone, yet it is so to a certain extent in cupellation, in consequence of the presence of lead. It is, therefore, necessary to make cupellations of the buttons from ores containing silver, at the lowest heat at which the absorption of the litharge can be readily determined. But even when every precaution is used, there is always a loss of silver in cupellation; and the amount of this loss under varying conditions must be known, so as to be able to supply the deficiency in the calculation of the per-centage, as well as with a view to the next process of *parting*. The following table has been calculated for this purpose. The first column gives the weight of silver in one thousand parts of an alloy of silver and copper about to be submitted to cupellation; the second, the actual weight of silver found by cupelling an alloy of silver and copper containing the weight of silver indicated in the corresponding line of the first column; and the third, the actual loss in weight of silver:—

Weight of silver before cupellation.	Weight of silver after cupellation.	Loss of silver
1000	998.97	1.03
975	973.24	1.76
950	947.50	2.50
925	921.75	3.25

25	24.78	.22

In assaying native gold or artificial alloys, the operation usually commences by fusing the alloy in a cupel with about five times its weight of pure lead, and then adding the amount of pure silver necessary to bring the mixture to the proper composition. If the substance be in the ordinary state of the gold of California or Australia, that is, in small grains or dust, it is the best plan to envelop it in a thin sheet of lead; or a suitable quantity of perfectly pure lead may be put into the cupel and melted, and then the assay, wrapped up in a piece of thin sheet assay-lead, may be gently added to the melted lead upon the cupel. Finally, add about three times the weight of the assay in pure silver, and then proceed with the cupellation in the manner above-described. The presence of iron, tin, nickel, or zinc, in the alloy under assay, materially interferes with the success of the operation, as these metals will not pass into the cupel by the aid even of a large quantity of lead; but from their rapid oxidation, will either volatilize, or will accumulate on the surface as a sort of slag, in which particles of precious metal may be entangled. In this case the assay becomes what is technically termed *foul*, the cupel not being able to absorb the metallic oxides as fast as they are formed. To obviate this evil, the preliminary process of scorification should be resorted to, when the presence in the alloy of any of the above metals is known or suspected. A convenient weight of native gold or rich alloy to operate upon is ten to fifteen grains.

Bismuth might be used as a substitute for lead in cupellation, two parts of it being nearly equivalent to three of lead; but its higher price prevents its general use for this purpose. The lead employed must be in all cases entirely free from silver, being such as has been revived from pure litharge, otherwise it would be quite impossible to estimate the true composition of the alloy. The assay of gold furnishes results which are more accurate than those obtained in the cupellation of silver; the loss of gold by volatilization is very much smaller, and scarcely any of the metal is carried into the cupel by an excess of lead.

Parting of the Assay.—After the preceding operations, the button of alloy which remains is composed of gold and silver, not, indeed, absolutely pure, for, whatever precautions may be used, it will still retain a small quantity of lead, and frequently, also, traces of copper. For practical purposes, however, it may be regarded as a pure alloy of the two precious metals, and in this view it now only remains to separate the gold from the silver. It has been stated that, on the Continent, this is effected on the large scale by means of sulphuric acid, which, at its boiling temperature, possesses the property of dissolving silver without acting upon gold. For analytical purposes, however, nitric acid is preferred, and is generally employed in this

country, even for refining operations on the large scale.

It has been stated, also, that when silver and gold are intimately mixed together, as in an alloy, it is necessary that the silver should be present in the proportion of at least two and a half parts of that metal to one part of gold, otherwise its particles will be so enveloped and protected by those of the gold, that the nitric acid will be prevented from exercising its solvent action upon them. If, as is generally the case, the requisite proportion of silver has been introduced before cupellation, or if it is known to exist in the alloy in that proportion, then it will be sufficient to subject the mixture at once to the action of the acid. But if the silver be present in a less or much greater proportion, then, as a preliminary step to the operation of parting, the alloy must be brought to the proper standard, either by the addition of the necessary quantity of pure silver, or by adding more gold, as the case may be; for if the proportion of silver exceed three parts, the gold will be precipitated by the acid as a dark powder, instead of retaining the more convenient form of the alloy subjected to treatment; and thus an accurate estimation of the amount of gold present will be rendered considerably more difficult.

On the whole, the operation of parting is found to succeed best when the alloy contains a little less than three parts of silver to one of gold. Hence, in all cases where much exactness is required, the addition of silver, if necessary, must be so managed as to agree as closely as possible with this proportion; and from the circumstance, that when the relative quantities of the two are so adjusted, the gold is present in the proportion of about one-fourth of the mass, and the silver in the proportion of three-fourths, the operation of bringing the alloy to the proper standard by the requisite addition of the latter metal, is termed *inquantation*. The quantity of silver required can only be known by a previous approximate experiment by the wet method of examination, or by the use of the touchstone.

Assuming that the proper proportion already exists in the button of gold and silver obtained by cupellation, it is first hammered out upon an anvil into a small disc about the size of a sixpence, and annealed by heating it to redness. It is then passed between a pair of laminating rollers, by which its thickness is reduced to that of an ordinary address card, or about one-eightieth of an inch, after which it is a second time annealed. These operations render it sufficiently flexible to allow of its being twisted into a small spiral coil or *cornet*,

Fig. 243.

by rolling between the finger and thumb. The cornet thus obtained is then introduced into a small parting-flask of the form represented in Fig. 243, which contains about an ounce of nitric acid of specific gravity 1.180. The acid must be perfectly *free from chlorine*, and must always be carefully tested to ascertain this point by adding to it a drop of solution of nitrate of

silver, which, if chlorine be present, will instantly render it milky. Instead of the flask represented in Fig. 243, a small bulb-shaped matrass is frequently used, and is now generally adopted by the best assayers of bullion, both on the Continent and in this country. Common Florence oil flasks, or smaller vessels of the forms represented in Figs. 244 and 245, will be found very convenient. When the

cornet has been introduced, the flask with its contents is gently heated to nearly the boiling-point. Effervescence will now take place, with a brisk evolution of nitrous fumes, and the silver will be gradually dissolved, leaving the gold in the form of the original cornet, but porous, very brittle, and of a deep blackish-brown color. When the effervescence has entirely ceased, the flask is removed from the heat, and the solution is carefully decanted off, without letting the cornet of gold fall out. The latter is then washed by pouring distilled water upon it, which, after standing for a couple of minutes, is again poured off. The gold will still retain some traces of silver, and in order to remove these, the cornet is again boiled with stronger nitric acid, of specific gravity 1.280, and this operation may even be repeated a third time, to remove the last portions of silver, which exist as a surcharge. In the second and third boilings, which may each be continued for ten or fifteen minutes, it is well to introduce into the flask a small fragment of charcoal, to prevent the ebullition from taking place with sudden bursts, otherwise the action may be so violent as to break the cornet, which it is desirable to avoid.

The last acid having been poured off, the flask is completely filled with distilled water, and a small, smoothly-finished, porous clay crucible is placed over the mouth of it. The two vessels, thus adjusted, are then inverted, so as to allow the cornet to fall gently through the water into the crucible, and by a dexterous movement of the hand the flask is withdrawn, in such a manner as to prevent the overflow of any liquid from the little crucible. The latter is now carefully decanted into the vessel containing the silver solution, and the crucible containing the cornet is heated to redness in the muffle. Under this final heating it is not fused, but shrinks in bulk, loses its brown appearance, and assumes the peculiar color and lustre of gold; while at the same time it is rendered more compact, less brittle and fragile, and when cold, can now be removed by a pair of forceps to the scales, in which it is weighed with the same precision and care as the original alloy.

The weight of the cornet will indicate very nearly the amount of gold in the alloy if the assay has been properly conducted, but not with absolute exactness. Even when every precaution has been used, the gold contained in the cornet is never chemically pure; it still retains a very small quantity of lead and of silver, and frequently also traces of copper, in consequence of which the weight of the cornet may exceed by one two-thousandth part the true result; and when it is considered that, in assaying alloys, the quantity taken

Fig. 244. Fig. 245.

is usually not more than seven or eight grains, it will be seen that even this small error might lead to serious disappointment in estimating the proportion of gold in large masses of bullion. To ascertain the amount of the error, and thus to arrive at a perfectly correct estimate, it is usual to pass through the muffle, simultaneously with the alloys, a number of what are termed *proofs*, consisting of weighed portions of perfectly pure gold, to each of which is added a proportion of copper equal to that estimated to exist in the alloys under examination. The cornets obtained from these proof-assays are weighed, and the excess of weight over that of the gold which was introduced, indicates the amount of the correction which it becomes necessary to make for the other assays. This correction is liable to variation, according to the temperature of the furnace, and other causes; but it usually ranges from 0.2 to 0.5 in 1000.

If the quantity of silver in the alloy submitted to the operation of parting exceed by more than thrice the weight of the gold, the separation may still be effected by nitric acid, but the gold will be left in a state of powder. It may, however, be washed, ignited, and weighed in the manner described in connection with the quantitative estimation of gold by the wet method, and also in the process of parting with sulphuric acid on the large scale. Should the amount of silver be but small compared with the gold, and the assayer wish to avoid the trouble of inquartation, the alloy may at once be subjected to the action of aqua regia, when the gold will be dissolved, and the silver will be thrown down as an insoluble chloride. The clear solution containing the gold is then decanted, and when the excess of acid has been expelled by evaporation, the gold can be precipitated, as already described, by sulphate of iron.

The silver contained in the solution of the nitrate of that metal obtained in the common process of parting, may readily be recovered by adding an excess of chloride of sodium, which will throw down the whole of the silver as white insoluble chloride. This precipitate, which speedily becomes slate-colored on exposure to light, is collected, and put into a vessel containing water acidulated with hydrochloric acid; some zinc or iron is introduced, and the silver is rapidly restored to the metallic state, in the form of a dark-grey powder. When this powder is washed with water, dried, and fused in a crucible, the silver assumes its natural appearance, but is very brittle. Its malleability is restored, however, by simply re-melting.

PHYSIOLOGICAL EFFECTS, et cetera.—Gold, says PEREIRA, like other metals, has been frequently supposed to be inert while it retains its metallic condition, but in this, as well as in some other instances, the accuracy of the assumption has been denied. Both CHRESTIEN and NIEL, as well as other writers, assert that finely-divided metallic gold—*pulvis auri*—produces the same constitutional effects as those caused by the various preparations of this metal, but in a milder degree, while it excites little or no irritation. It is said to promote the secretions of the skin, kidneys, and salivary glands.

It has been employed as an antivenereal and antiscrofulous remedy, by CHRESTIEN, NIEL, and others,

with considerable success. It is said to be preferable to the other preparations of this metal in delicate and nervous subjects, females and infants. Gold-leaf—*aurum foliatum* seu *lamellatum*—is used by dentists for filling decayed teeth, and was formerly employed by apothecaries for covering pills—*ad inaurandas* seu *obducendas pilulas*. Silver-leaf now takes its place. It has been administered internally in doses of from a quarter of a grain to a grain three or four times a day. CHRESTIEN used it by way of friction on the tongue and gums. NIEL employed it endermically—that is, applied it to the skin deprived of the epidermis—in the form of ointment composed of one grain of gold and thirty grains of lard.

Teroxide of gold is sometimes used internally, in venereal and scrofulous diseases, in doses of from one-tenth of a grain to a grain, made into the form of pills with mezereon.

The terchloride of gold, the preparation of which is described at page 293, acts, according to ORFILA, as a corrosive when introduced into the stomach of animals, but with less energy than the chloride of mercury, and destroys them by the inflammation of the coats of the alimentary canal which it sets up.

On man its effects are analogous to those of chloride of mercury. In *small doses* it acts, according to Dr. CHRESTIEN, more energetically as a stimulant, though less powerfully as a sialogogue, than corrosive sublimate. It promotes the secretions of the skin, the salivary glands, and the kidneys. Taken to the extent of one-tenth of a grain daily, it has occasioned violent fever. CULLERIER has seen one-fifteenth of a grain excite, at the second dose, gastric irritation, dryness of the tongue, redness of the throat, colic, and diarrhoea. When it promotes the secretion of saliva, it does not as mercury affect the teeth and gums. MAGENDIE has seen violent gastritis, accompanied by nervous symptoms—cramps and pains in the limbs, agitation and loss of sleep—and afterwards great heat of skin, and obstinate sleeplessness. In *large doses*, it would probably occasion symptoms similar to those produced by the use of poisonous doses of chloride of mercury.

It has been employed, with variable success, as a substitute for mercury in the secondary symptoms of syphilis. A more extended experience of it is, however, necessary to enable one to speak of its remedial powers with confidence. In the hands of CHRESTIEN, NIEL, CULLERIER, LEGRAND, and others, it has proved most successful.

It has also been used in scrofulous affections, bronchocele, chronic skin diseases, scirrhus tumours, et cetera. DUPORTAL cured with it a case of obstinate ulceration of the face, regarded by him as cancerous and which had resisted all the ordinary methods.

LEGRAND has used terchloride of gold, acidified with nitric acid, as a caustic in syphilitic, scrofulous, and scorbutic ulcers, cancerous growths, and ulcerations of the neck of the uterus.

Internally, it has been given in doses of one-twentieth of a grain, made into pills with starch. But as organic matters decompose it, it is better to use it in distilled water, or to apply it by friction to the mouth, in quantities of from one-sixteenth to one-sixth of a grain.

The whites and yolks of eggs, milk, and a mixture of wheat-flour, oatmeal, or barley, and water, are, as in the case of chloride of mercury, antidotes for an overdose of this auric compound.

The Editor is surprised to find that the above are so little used in medicine. Surely, if physicians would only daily experiment on the action of the different metals and their compounds upon the system, they might soon discover some more very valuable specifics.

STATISTICS.—Gold and silver are frequently confounded in statistical returns under the common designation of the *precious metals*; and even where the two are classed separately, it is still desirable to place them in juxtaposition, since much of the interest attaching to the subject is derived from the relation which they bear to each other. In proceeding, therefore, to state the most important facts connected with the statistics of gold, the Editor will give, at the same time, most of the corresponding facts and figures relating to silver; which will not only save the repetition of a number of tables nearly similar, but will furnish the reader with a clearer and more satisfactory view of the subject, than if the returns relating to each of the metals were tabulated separately in different parts of the work.

Much interesting information relating to the history and statistics of the precious metals is given in a work which was published by Mr. JACOB in 1831, in which he takes up the subject at the earliest period, and continues it to the year above-mentioned. Mr. JACOB shows that, in the days of Roman supremacy, the greater part of the wealth of the world continued to flow into Rome, up to the time of AUGUSTUS, when the production of gold from the Roman mines in Illyria and Spain suddenly ceased; and for a long period the world received no new accession of metallic wealth. With much labor and research, he constructed a table showing the rate of diminution to which the enormous wealth of the Augustan period was subject; and though it includes both gold and silver under one head, while at the same time its accuracy cannot be implicitly relied on, still it is sufficiently correct and instructive to merit a place in these pages:—

QUANTITY OF GOLD AND SILVER IN THE ROMAN EMPIRE.

Year,	
14	£358,000,000
50	322,200,000
86	287,980,000
122	259,182,000
158	233,263,800
194	209,937,420
230	181,943,678
266	163,749,311
302	147,374,380
338	132,636,942
374	119,373,248
410	107,435,924
446	96,692,332
482	87,033,099
518	78,229,700
554	70,406,730
590	63,364,057
626	57,027,652
662	51,324,887
698	46,192,399
734	41,573,160
770	37,415,840
806	33,674,256

From the decline and fall of the Roman empire, the

portion of gold added to that already obtained was, for many centuries, not more than sufficient to supply the annual waste by wear and loss; and except the mines of Hungary and Sweden, which do not appear to have been worked before the eighth or ninth century, no important new sources of gold were opened until the discovery of America by COLUMBUS in 1492. This event was followed, in the course of the next century, by a considerable influx of the precious metals into Europe; yet a very superficial inquiry will suffice to show, that the actual amounts which were imported from Mexico and South America have been greatly exaggerated in the public mind, and sink into very humble figures when compared with the enormous treasures obtained within the last few years from California and Australia. From 1492 to 1500, America, according to HUMBOLDT, furnished to Europe, in gold and silver, not more than fifty-two thousand pounds sterling, and the entire annual amount of gold and silver obtained from America during the sixteenth century was only about half a million sterling; whereas, for the last few years, the value of *gold alone* exported from California and Australia has averaged twenty-four millions per annum. The celebrated *El Dorados* of the sixteenth century sink, therefore, into utter insignificance, compared with the recently-developed auriferous regions.

It is true, that with the discovery of the Brazil mines and other sources, the import of the precious metals from America continued steadily to increase; and from 1600 to 1700, during which period Europe obtained its supply of gold almost exclusively from the New World, the mines of the latter were estimated to have produced an amount of gold and silver equivalent to three hundred and thirty-seven millions, five hundred thousand pounds sterling, or upwards of three millions per annum. In consequence of this continued importation, the value of the coined money in Europe in 1699 has been estimated at two hundred and ninety-seven million pounds sterling. During the eighteenth century, the supply of the precious metals was still chiefly derived from the Americas. The annual produce of the mines of that quarter of the globe, at the commencement of the present century, was estimated by HUMBOLDT at eight millions, seven hundred thousand pounds sterling; and that derived from the European mines of Hungary, Saxony, *et cetera*, and those of Northern Asia, was valued by him at one million pounds sterling more, raising the total produce at that period, exclusive of Africa, to nine million seven hundred thousand pounds sterling. The *quantity* of gold produced in America was to the *quantity* of silver as 1 to 46; in Europe as 1 to 40; and the *values* of equal quantities of gold and silver were then in the proportion of 15 to 1, so that the aggregate value of the gold to that of the silver was nearly as 1 : 3; or, in other words, the annual amount of *gold alone* produced at the beginning of the present century was worth about three million two hundred thousand pounds sterling.

From 1800 to 1810 the yield of the American mines continued still to increase, and, in conjunction with that of the European and Russian mines, is supposed to have amounted in the latter year to upwards of eleven million pounds sterling, in gold and silver. But in that

year began the contest which resulted in the dissolution of the connection between Spain and her American colonies, causing the abandonment of several of the mines, and a consequent decline in the production of the precious metals to such an extent, that, according to JACOB, the total average yield of the American mines, inclusive of Brazil, during the twenty years ending with 1829, might be estimated at little more than four million pounds sterling a year; being less than half their produce in 1800. Some years later, however, they again began to increase; and this, in conjunction with the recent extraordinary development of the Russian

mines, raised the entire amount of gold and silver produced from all the *known* auriferous localities throughout the world, *before the discovery of California and Australia*, to upwards of twelve million pounds sterling per annum; the value of the gold to that of the silver being nearly as 5 : 6. This will appear from the following table, prepared by Mr. BIRKMYRE, showing, by approximate calculation, the annual produce in value of fine gold and silver for 1846 and 1850; the first being two years before the discovery of the rich deposits of gold in California, the latter two years after the discovery:—

The various countries are exclusive of China and Japan, which produce large quantities of gold and silver, the amount of which is quite unknown to Europeans.

It will be seen from the above table, that in 1846 the total value of the gold is estimated at five million, eight hundred and forty-six thousand, seven hundred and fifty-two pounds sterling; in 1850, it rises to eighteen million, six hundred and fifty-four thousand, five hundred and twenty-two pounds sterling. Mr. BIRKMYRE, however, estimates the produce of California alone in the last-mentioned year at twelve million pounds ster-

ling—a figure so high that, notwithstanding the importance attached by MACCULLOCH to his calculations, it seems to have far exceeded the truth. This may be inferred from the following table, extracted from the *Economist* newspaper, which has the credit of deriving its statistical information from the highest official sources:—

TOTAL VALUE OF GOLD EXPORTED FROM AUSTRALIA AND CALIFORNIA IN EACH YEAR FROM 1848 TO 1856 INCLUSIVE.

Year.	New South Wales.	Victoria.	California.	Total.
1848	—	—	£11,700	£11,700
1849	—	—	1,600,000	1,600,000
1850	—	—	5,000,000	5,000,000
1851	£468,336	£438,777	8,250,300	9,157,413
1852	3,600,175	6,135,728	11,700,000	21,435,903
1853	1,781,171	8,664,529	12,500,000	22,945,700
1854	773,209	8,255,550	14,100,000	23,128,759
1855	209,250	11,303,980	13,400,000	24,913,230
1856	97,456	12,643,024	14,000,000	26,740,480
Total,	£6,929,597	£47,441,588	£80,562,000	£134,933,185

To bring down the accounts to the latest date, the following table of imports, also resting on high authority, may be added:—

IMPORTS OF GOLD AND SILVER INTO GREAT BRITAIN FOR THE FIRST SIX MONTHS OF THE YEAR 1857 WERE—

From	
Africa,.....	gold £52,000
United States, including principal imports from California,.....	3,252,000
Australia,.....	5,833,000
Brazils,.....	6,000
Mexico, West Indies, Peru, and a portion from California,.....	gold and silver 3,415,000
Mediterranean,.....	543,000
Russia,.....	119,000
	£13,220,000

It will be observed, however, that these figures include both silver and gold, and indicate merely the amount of the precious metals imported into this country. But when it is considered that nearly the whole of the Australian produce is in gold, and that it is almost exclusively exported to Great Britain, the amount above stated as having been imported from that part of the world during the first six months of the present year, seems to indicate a falling-off as compared with the amount exported in 1856. This decline has been acknowledged by Australian journalists, but is attributed to temporary causes—the employment of larger numbers of the mining population than at any former period in deep sinking and in quartz mining, their consequent withdrawal from the immediate production of gold, and the protracted dryness of the season. The same writers affirm, that when the labor of the deep sinkers has been consummated, and the hoards of the shallow sinkers have passed through the process of washing, the average of the returns of the current year will be brought up to that of last. The steadiness with which the quartz reefs are being opened up at a heavy cost of labor and of money, and the large sums expended in machinery for the extraction of the metal, are deemed sure indications of the faith entertained by practical men in the hidden riches of the Australian gold mines.

On the whole, the present annual supply of gold may be roughly estimated as follows:—

Asiatic Russia,.....	£4,000,000
Rest of Asia—exclusive of Japan and China,.....	500,000
Europe,.....	300,000
Africa,.....	200,000
North and South America—exclusive of California,.....	1,500,000
California,.....	14,000,000
Australia,.....	13,000,000
Total,.....	£33,500,000

The annual consumption of *gold and silver* in the arts, and as coin or currency, is estimated by MACCULLOCH as follows:—

Wear and tear and loss of coin,.....	£5,700,000
Increase of currency,.....	11,400,000
Used in the arts,.....	11,200,000
Total,.....	£28,300,000

In connection with the subject of coinage, it may not be out of place to append the following tables, which would be obviously divested of much of their interest by giving the gold coinage alone:—

I. AMOUNT OF GOLD, SILVER, AND COPPER MONIES COINED AT THE ROYAL MINT, LONDON, FROM 1840 TO 1856.

Years.	Gold.	Silver.	Copper.	Total.
1840 ..	Nil	£216,414 ..	£3,136 ..	£219,550
1841 ..	£378,472 ..	96,175 ..	8,848 ..	483,495

Total,....£4,640,946£34,815,786£39,456,732

Annexed are some of the rates of value of a pound troy of gold at different periods:—

VALUE OF THE TROY POUND OF GOLD.

Years.	
1344	£15 0 0
1345	13 3 4
1347	14 0 0
1412	16 13 4
1464	20 16 8
1526	27 0 0
1549	34 0 0
1605	40 10 0
1626	44 10 0
1718	46 14 6
1817	46 14 6

which is the price at which fine gold still continues, or three pounds seventeen shillings and tenpence half-penny per ounce.

Mr. HUNT states, that for the uses of the arts not less

than one thousand ounces of fine gold are used in Birmingham alone every week, and that in the United Kingdom the weekly consumption of leaf-gold is as follows:—

	Ounces weekly
London,	400
Edinburgh,	35
Birmingham,	70
Manchester,	40
Dublin,	12
Liverpool,	15
Leeds,	6
Glasgow,	6
Total,	584

Of this amount, he states, on the authority of an eminent gold-refiner, that not one-tenth part can be recovered; and he adds, that for gilding metals by the electrotype, and the water or wash-gilding processes, not less than ten thousand ounces of gold are required annually. One establishment in the Potteries employs three thousand five hundred pounds' worth of gold per annum, and nearly two thousand pounds' worth is used by another. The consumption of gold in the Staffordshire Potteries for gilding porcelain and making crimson and rose color, varies from seven thousand to ten thousand ounces per annum.

The Editor has to express his obligations to Mr. GEORGE BLAIR of Glasgow for his valuable aid during the compilation of this article.

GUMS.—*Gommes*, French; *Pflanzenschleimen*, *Gummi*, German; *Gummi*, Latin.—Under the term gum, says BRANDE, are included several modifications of a distinct proximate principle of vegetables, which are of extremely common and almost universal occurrence. To some of these, the term *mucilage* is occasionally applied.

They are characterised by forming a viscid, mucilaginous, or adhesive solution with water, and by insolubility in alcohol, so that the addition of the latter to a moderately strong aqueous solution of gum occasions the separation of a white precipitate or magma. Another characteristic of gum is its convertibility into mucic or sacclactic acid by the action of nitric acid.—*Brande*.

Gum is found upon the bark of certain trees as an exudation, which gradually concretes in transparent or translucent amorphous drops. It may also be detected, in greater or less quantity, in the juices of most plants and fruits.

The several species of gums are distinguished by their behavior with water. Some dissolve in that liquid, and form *mucilages*, as gum-arabic; while others soften and intumescence, as tragacanth. But there is also an intermediate kind, represented by cherry-tree gum, which is only partially dissolved in water. These different classifications of gums have been denominated *arabin*, *tragacanthin*, and *cerasin*—from the Latin *cerasus*, a cherry-tree.

GUM-ARABIC—*Gomme Arabique*, French; *Arabischegummi*, German; *Gummi Acacia*, Latin—is the produce of the *Acacia Vera Arabica*, and other varieties. Many have supposed the *shittah* tree, mentioned in many parts of the Old Testament, especially in connection with the building of the tabernacle, to have been an acacia; some have regarded it as the *A. Vera*,

while others have thought it to have been the *A. Horrida*.

Dr. ADAM CLARKE, in his comment on Exodus, xxv. 5, says:—The *Acacia Nilotica*, or *A. Arabica*, is known to have been plentiful in Egypt, and it abounds in Arabia Deserta, the very place in which MOSES was when he built the tabernacle; and hence it is reasonable to suppose that he built it of that wood, which was every way proper for his purpose, being solid, light, and very beautiful.

HIPPOCRATES mentions *Egyptian acacia*, and the *white acacia*, by which, it is supposed, he meant the *acacia vera*. DIERBACH, however, thinks that the *Acacia Senegal* is referred to, from the fact that the wood, bark, and flowers of the latter are white. Gum is also named by HIPPOCRATES as being employed in medicine.

PRODUCTION.—The gum of the acacia trees flows, in the liquid state, from the trunk and branches, and hardens by exposure to the air. It usually exudes spontaneously, but, in some instances, the discharge is facilitated by incisions. In Barbary, the largest quantity of gum is procured during the hot and parching months of July and August. The more sickly the tree appears, the more gum it yields; and the hotter the weather, the more prolific is it. A wet winter and a cool or mild summer are unfavorable to the production of gum. In Senegal the gum begins to flow when the tree first opens its flowers, and it continues during the rainy season till the month of December, when it is collected for the first time. Another gathering of the gum is made in the month of March from incisions in the bark, which the extreme dryness of the atmosphere at that time is said to render necessary.—*Pereira*.

DESCRIPTION.—Gum-arabic occurs in globular pieces or *tears*, which are colorless or light yellow, more or less transparent, inodorous, and somewhat brittle. The following description of the most important varieties of acacia gum, is extracted from PEREIRA'S *Materia Medica*:—

Turkey or *Arabic Gum* is imported from Leghorn, Malta, Trieste, Gibraltar, Smyrna, Alexandria, Constantinople, *et cetera*, and is the produce of the *Acacia Vera*, and probably of other species, especially *A. Arabica*. It occurs in rounded tears, or amorphous or angular fragments, varying from the size of a pea to that of a walnut, or even still larger; some of the pieces being transparent, others more or less opaque, from innumerable cracks extending through them. It has a glassy lustre, is white, yellow, or sherry colored, and has no odor, or, if any, an acid one. Its specific gravity varies from 1.316 to 1.482. It is entirely soluble in water, the solution having the property of reddening litmus, and being feebly opalescent. The latter characteristic is said by GUERIN to be owing to the presence of a small quantity of insoluble nitrogenous matter.

Barbary or *Morocco Gum* is imported from Mogadore and Mazagan. It is probably the produce of *Acacia Gummifera*. Dr. PEREIRA had two varieties of Barbary gum; one in roundish or irregular tears, mixed with many impurities, imperfectly transparent, and of a dull yellowish color, with a faint tint of green. It

was not wholly soluble in water. The other kind, called Mogadore gum, is in small, irregular, broken, mostly yellow pieces, which resemble fragments of Turkey gum.

Gum-senegal is imported from St. Louis, St. Mary's, the river Gambia, Senegal, and Bathurst, and is probably obtained from several species of acacia; but especially *A. Senegal*, *A. Vera*, *A. Serjal*, and *A. Adansonii*, are said to produce it in part. It occurs in larger tears than those of Turkey or Arabic gum, and large air cavities are frequently found in their centres on breaking them. Whitish pieces are occasionally met with, but for the most part they are yellow, reddish-yellow, or brownish-red. More difficulty is experienced in breaking or pulverizing this gum than gum-arabic, and its fracture is more conchoidal. GUIBOUT distinguishes two varieties of this gum: the first, gum-senegal, properly so called, probably the produce of *Acacia Senegal*; while the second, gum-galam, is yielded by *A. Vera*. There is but little difference between them, yet the latter has a greater resemblance to Turkey gum than the former. The pieces of gum-galam are more broken, and therefore more brilliant than those of gum-senegal. Those tears or fragments which have on some part of them a yellowish opaque skin or pellicle, constitute the *Gomme pelliculée* of GUIBOUT. The *Marrons de Gomme*, or *Gomme lignirode* of the same pharmacologist, is also found in the Senegal gum of commerce; it consists of yellowish or dark-brownish pieces, which are difficult to break, opaque, and rough. Treated with water, it is only partially dissolved. GUIBOUT states, that in most of the *marrons* he found a large ovoid cell, which had evidently been the habitation of some larvæ, whence he concludes that this substance is the work of an insect.

East India Gum is imported principally from Bombay, and is most likely the produce of various species. Many pieces—yellow East India gum—agree in their physical and chemical characters with Turkey gum, and are probably the produce of *Acacia Arabica*, or some allied species. Others, however, are larger, red, or brown—brown East India gum—and more difficult to pulverize than Turkey or Arabic gum.

Cape Gum is imported from the Cape of Good Hope; BURCHELL states that it is obtained from a species of acacia, closely resembling *A. Vera*, and which he denominates *A. capensis*. Notwithstanding that the last-named authority asserts, that the Cape gum is in no way inferior to that from *A. Vera*, it is considered by English dealers as a very inferior kind. It is pale yellow, and apparently resembles Mogadore gum mentioned previously, or small fragments of Turkey gum. It is collected by the Caffres.

PROPERTIES AND COMPOSITION.—Gum-arabic dissolves both in cold and hot water. If this solution be allowed to evaporate spontaneously, the gum is left apparently dry, but, in reality, in a hydrated state, retaining about seventeen per cent. of moisture. If heated slightly above 212° , the color of the gum becomes yellow, and it has an acid taste. When distilled destructively, the products are empyreumatic oil, acid water, carbide of hydrogen, carbonic acid, and a charred mass; the latter leaving, upon ignition, about three per

cent. of inorganic matter, composed of carbonates of potassa and lime, with minute portions of chloride of potassium, oxide of iron, aluminum, magnesia, and silicic acid.

Gum is thrown down from its aqueous solution by alcohol as a white magma. Tribasic acetate of lead—but not the neutral acetate—occasions a white precipitate, which BERZELIUS denominated *gummiæ of lead*. A concentrated solution of sesquichloride of iron causes, when dropped into a gummy menstruum, a brownish translucent gelatinization. Silicate of potassa and oxalate of ammonia produce white deposits, the reaction with the latter being caused by the lime present. Caustic potassa, according to BERZELIUS, first causes in strong solutions of gum a coagulum, which gradually liquefies. A solution of borax occasions in that of gum-arabic, a coagulation which dissolves in free acid. Gum, in this instance, gives a reaction similar to that afforded by starch.

On the trituration of powdered acacia gum with a sufficient quantity of sulphuric acid to form a pasty mass, the mixture soon acquires a brown color; and if it is allowed to stand for about twenty-four hours, then liquefied with water, and carbonate of lime added to unite with the acid, the gum which remains dissolved is considerably changed in character and properties. If, on the contrary, sulphuric acid and gum be mixed, the latter is decomposed with evolution of sulphurous acid, and the production of artificial tannin and a scarcely appreciable amount of acetic acid. Upon adding water after this reaction, about thirty per cent. of carbon is deposited. The ebullition of gum with *very attenuated* sulphuric acid, gives rise to the formation of glucose or grape sugar.

Gum is decomposed by nitric acid, and, on the application of heat, nitric oxide is set free, and *muic acid* deposits as the temperature of the mass becomes reduced. On carrying the decomposition further, malic and oxalic acids may be detected.

According to VAUQUELIN, when a solution of gum is subjected to the action of a stream of chlorine gas, citric acid is formed; but this statement is very questionable. Chlorine is absorbed by powdered gum, causing the latter to soften and become brown. Hydrochloric acid is also absorbed by gum; the latter becomes brown and glutinous; and, on the addition of sulphuric acid to the magma, hydrochloric acid gas is evolved.

Gum has been analysed by BERZELIUS, PROUT, GUERIN, MULDER, and many others. The following are some of the results of the examination of gum-arabic:—

	Centesimally represented.		
	Berzelius.	Prout.	Mulder.
Carbon,	41.906	41.4	45.10
Hydrogen,	6.788	6.5	6.10
Oxygen,	51.306	52.1	48.80
	100.000	100.0	100.00

The analyses of BERZELIUS and PROUT give rise to the formula, $C_{13}H_{13}O_{12}$. That deduced from the results of MULDER is $C_{12}H_{10}O_{10}$. But LIEBIG adopts the formula, $C_{12}H_{11}O_{11}$, and represents it as a hydrate of carbon, C_{12} , 11 HO, and these views are supported

by the composition of the compound of gum with oxide of lead, as ascertained by BERZELIUS:—

	At. weight	Theory.	Centesimally.
1 Eq. Oxide of lead, { 1 Eq. Lead, 104 } { 1 Eq. Oxygen, 8 }	112	39.58	38.25
1 Eq. Gum, { 12 Eqs. Carbon, 72 } { 11 Eqs. Hydrogen, 11 } { 11 Eqs. Oxygen, 88 }	171	60.42	61.75
1 Eq. Gummiæ of lead,	283	100.00	100.00

Fine gum-arabic consists almost entirely of *arabin*, the other constituents being the inorganic matter and moisture.

Pure arabin may be obtained by making a clear aqueous solution of gum, and adding alcohol, when the arabin is thrown down. It is an uncrystallizable amorphous solid, devoid of color, taste, or smell; soluble in water, whether cold or hot, but not taken up by ether or oils. It unites with alkalies. According to GUERIN, arabin consists of—

	Centesimally.
Carbon,	43.81
Hydrogen,	6.20
Oxygen,	49.85
Nitrogen,	0.14
	100.00

But it is clear that this analysis must be wrong, since gum itself contains no nitrogen, and no substances containing this element are required in the preparation of arabin. According to the same authority, gum-arabic contains 79.4 per cent. of arabin.

USES.—Gum-arabic is employed in medicine as an emollient and demulcent, but more frequently as a vehicle for the exhibition of other medicines. It is sometimes slowly dissolved in the mouth to allay troublesome cough, and to diminish irritation of the fauces, by diluting the acid secretions, and sheathing the part from the action of the atmosphere. In inflammatory affections of the intestinal tube, as well as of the respiratory and urinary organs, gum is employed as a demulcent and emollient. A solution of gum may be used as a sheathing substance in cases of acrid poisoning; but its efficacy is believed to be owing to mechanical properties merely. In the state of powder, gum is occasionally employed to check hemorrhage from leech bites. As a vehicle for the administration of other medicines, it is used either in powder or mucilage—in the former condition to give bulk to active and heavy powders, as subchloride of mercury, tartrate of antimony and potassa, *et cetera*, and in the preparation of lozenges; in solution, to suspend insoluble powders—as oxide of zinc or musk—in water; or to diffuse oily and resinous substances through aqueous fluids, and to give form and tenacity to pills. Furthermore, adds PEREIRA, it is exceedingly useful for various other pharmaceutical purposes, although it is now generally superseded by dextrin.

Its property of suspending fine powders or precipitates in solution, has caused its use in the manufacture of inks; and its clamminess when moist, and firmness when dry, have given rise to its application for cementing or pasting paper or other light articles which are not to be exposed to moisture.

ADULTERATION.—Gum-arabic, says NORMANDY, is

often adulterated with gum-senegal, which has almost the same appearance, and altogether the same qualities as the former; the latter being considerably cheaper, those pieces which are small, light-colored, dry, easily broken, and which, in fact, most resemble gum-arabic, are mixed with it, and sold as such.

It is sometimes also mixed with common cherry-tree gum; but this is generally in dark-brown irregular masses, difficult to break, and when thrown into water they swell and separate from the homogeneous mucilage afforded by the genuine gum in gelatinous clots. This is equally effective as a test, whether the gum is or is not pulverized.

Gum-arabic when ground is in the state of a white powder, and is consequently sophisticated with starch and flour, and the gum generally is altogether replaced by gum-senegal, or partly by cherry-tree gum.

Gum-senegal itself is often mixed, both when in tears and when ground, with cherry-tree gum.

The presence of starch and flour may be readily detected by boiling a small quantity of the suspected gum in water, and testing the mucilage, when it has become cold, with iodine, which imparts to starch an intense blue or violet hue.

PURIFICATION.—A patent was granted, in the year 1848, to M. H. PICCIOTTO, for two several methods of purifying and decoloring all varieties of gum-arabic. The first of these is as follows:—

A rather strong solution of pure sulphurous acid gas is prepared by one of the ordinary methods, and protected as much as possible from the contact of atmospheric air. In each six to twelve parts of this solution, one part by weight of gum, either in its natural state or in powder, is introduced. When it has dissolved, it will be found that the greater portion of its coloring matter will have been destroyed, or has chemically combined with the sulphurous acid, forming a colorless compound.

The sulphurous acid may be brought into contact with the gum by other methods than the one just described, as by passing a current of the gas into a concentrated solution of gum, or by introducing the gas into a close receiver, surrounded with a refrigerating substance or mixture; in which case, by the action of the cold and the pressure of the gas itself, it will be condensed into a fluid, and in this state may be commingled with a solution of gum.

Various processes may be resorted to for the removal from the solution of gum, of the free acid, or the acid combined with the coloring matter; but the patentee prefers the following:—

Heat is applied to the close vessel containing the menstruum, during which time the portion of gas evolved may pass through a tube into another receiver containing water, and thus be recovered for another operation. The hot mixture is then run off in small portions into a larger and open vessel, containing a slight excess of some salifiable base, which, in its combination with sulphurous acid, will form an insoluble salt. For this purpose, carbonate of baryta is to be preferred, as both the sulphite and sulphate of baryta are insoluble. The combination is aided by agitation, and when the whole of the disengaged car-

bonic acid gas has been driven off, and the solution has become neutral, it is allowed to rest for some hours—the vessel being covered—so that the coarser parts of the solid matter may be deposited. The neutralization of the acid may also be effected without previously heating the liquid; but then the patentee recommends that it should be heated after the combination has taken place, so that the whole of the carbonic acid, which might retain in solution a small portion of undecomposed carbonate of baryta, may be evolved.

The menstruum is now to be filtered, in order to remove the sulphite of baryta and other insoluble impurities. The filter employed by the patentee is a thin layer of pure gelatinous hydrate of alumina laid on cloth; but the liquid may also be forced through unglazed earthen or stone ware. After the solution has percolated either of these media, it will be found that all ligneous fibre, silicious and earthy matters, and all particles of insoluble gum have been separated and deposited on the vessels and filter employed, and very little color will remain in the depurated solution; but when a very white gum is required, the process of acidulation must be repeated. By evaporating the filtered menstruum, a colorless, tasteless, and pure gum is obtained, the natural properties of which have not been in the least degree altered.

The sulphurous acid gas may be separated from the solution of gum, without neutralizing it by means of a base, by boiling the mixture in a close air-tight vessel, and conducting the evolved gas into a receiver containing water. If required, the bleaching process may be repeated, by introducing a current of pure sulphurous acid gas into the vessel containing the solution, and then removing it by ebullition. When the menstruum has become cool, it will be found that all the impurities originally united with the gum are deposited at the bottom of the vessel, and the pure solution may be drawn off; or the whole contents of the vessel may be emptied into cloth bags, when the fluid portion will percolate.

The second process is given underneath:—

The gum is dissolved in from six to fifteen parts of hot or cold water, and the solution filtered through cloth. A quantity of pure gelatinous hydrate of alumina is then thoroughly incorporated with the menstruum so as to form a thin homogeneous paste, and this being placed on cloth, a pure and greatly decolorized liquid of gum will percolate. Instead of making the mixture just described, the simple solution of gum may be passed through a bed of alumina alone, or the latter with other substances; and, more time being allowed for the filtration, the decoloration will be quite as well effected. If a perfectly white gum is required, it will be essential that the process be again repeated; but as the second and third portions of alumina, after being used, contain very little tinctorial matter, they may serve again for the first decoloration of another quantity of gum. When the hydrate of alumina becomes highly tinged, it is washed with hot water on a filter, to separate the gum from it; after which it is edulcorated with a cold limpid solution of chlorine or chloride of calcium, filtered, and then repeatedly subjected to the action of a stream of hot water.

By these means, not only its original whiteness and purity, but also its chemical affinity for tinctorial matter, are restored.

STATISTICS.—Gum-arabic is imported either direct from Alexandria, Smyrna, Tripoli, Mogadore, Tangiers, *et cetera*; or second-hand from those places through Gibraltar, Malta, and the Italian ports.

Previously to the year 1842, the duty on gum-arabic from *British colonies* was six shillings per hundredweight; from other parts twelve shillings; but the duty was then fixed at twelve shillings per hundredweight upon all gums, of whatever origin, and this was subsequently reduced to one shilling upon the same quantity. Of twenty-five thousand, two hundred and eighty-nine hundredweight imported in 1839, Tripoli, Barbary, and Morocco furnished four thousand five hundred and eighty-seven; Turkey, four hundred and thirteen; and the Cape of Good Hope, two thousand seven hundred and thirteen, while fifteen thousand four hundred and thirty-one hundredweight were from the East Indies.

The trade in gum-senegal is principally in the hands of the French.

AUSTRALIAN GUM.—In 1848, Dr. HOFFF received a gum, purporting to be from Australia, which consisted of reddish-brown and brownish-yellow pieces, mostly semiglobular, tear-shaped, and moderately transparent, to which the bark was partly adhering. Internally this gum was much cracked. It was not hygroscopic, was easily pulverized, glittered like glass, and furnished a slightly colored powder. Its aqueous solution had no peculiar taste; when diluted to such an extent that it could be filtered, it gave the following reactions:—

Basic acetate of lead caused a brownish turbidity; subnitrate of mercury produced a greyish opalescence; nitrate of mercury gave a similar, but less decisive reaction; chloride of mercury occasioned no change; iodine scarcely tinged the menstruum.—*Pharmaceutical Journal*.

From the above characteristics it will be seen, as Dr. PEREIRA has remarked, that the Australian gum bears more resemblance to that of the cherry-tree than that of the acacia.

GUM-BASSORA, though described by continental pharmacologists, seems to be new, of nearly so, in British commerce. According to Dr. PEREIRA, it occurs in variable-sized pieces, which are whitish or yellowish, and opaque. It appears to belong to the Bassorine class, as when put into water, it swells up, but dissolves only in part. Its origin is unknown.

BRITISH GUM.—*Artificial Gum—Torrefied Starch—Dextrin*.—Under these names a modification of starch is known, which is often prepared in the following manner:—

Well-dried starch is heated to 300° in sheet-iron trays, when it intumesces, giving off vapors and the odor of highly-baked bread, and forming yellowish-brown masses. This, when ground, is employed as a substitute for tragacanth, senegal, and similar gums, in the dressing, stiffening, glazing, sizing, dyeing, printing and finishing calicos, nets, crapes, laces, silks, papers, and all goods of a similar kind.

Starch, when submitted to the above process, is converted into a gummy substance, which, having lost all gelatinous properties, is soluble in either cold or hot water; and iodine, instead of causing a blue color, as with unaltered starch, communicates to it a dingy purple tint.

It possesses the characteristic property of turning the plane of polarization to the right when acting on polarized light, and is consequently sold in Paris under the name of *dextrin*.

British gum or dextrin is now met with in commerce in three distinct forms; namely, as a white, brilliant, and pearly powder; as a sirupy solution; and in the form of exotic gum, in greater or less perfection, either broken into small fragments, or made into rolls of various sizes.

Formerly, it was only produced in the first condition, that of powder; and if some manufacturers have attempted to impart to it the appearance of the product for which it is so much substituted, they may have been induced to do so from the conviction, that the only way to supersede the old plan was by humoring and even deceiving its consumers with the outward appearance of the old product.

It has since been discovered, that many advantages, not primarily expected, are attendant on the communication to dextrin of the form and appearance of natural gum. It is easily dissolved, and makes a clear solution; in the state of powder it possesses the superiority over dextrin of being more readily packed; and over liquid gum, the advantage of not fermenting.

A misapprehension seems to have been entertained, that, taking advantage of the resemblance, the exotic would be adulterated with the artificial product. Fortunately this is impracticable, as the smell and taste of potato oil, which always accompany artificial gum, are sufficient to betray its presence; and thus, if the purchaser suspects fraud, the most ready means for its detection are in his possession, and may be at once applied.

British gum may be prepared by many other processes than the one just described. Besides being procured by torrefaction, it is also obtainable, either by the use of acids, or by means of diastase.

PAYEN discovered a method which furnishes a whiter and more soluble product than can be obtained by torrefaction. It consists in moistening one thousand parts of *dry* starch—potato-starch is generally used—with very dilute nitric acid, consisting of two parts of the concentrated acid to three hundred of water. The mass is then divided into small blocks, which, when exsiccated in the air, are rubbed down, and exposed in a proper stove to a current of air heated to about 150° or 160°. The powder is ultimately well dried at a temperature not exceeding 230°. When well made, it dissolves in cold or slightly warmed water, with the same facility as gum. The modified starch obtained by this mode has been also called *leiocom*.—*Brande*.

A patent was granted in May, 1845, to J. F. PINEL, for improvements in the method of treating farinaceous matters for the production of British gum. The *modus operandi* is as follows:—

Half a gallon of nitric and half a pint of hydrochloric acid are mixed with one hundred gallons of spring water, and as much flour or fecula being then added as is sufficient to form a paste, the whole is well worked together, and left for two hours to settle. After the expiration of this time, the paste is carefully removed into buckets properly prepared for allowing the water to drain off. When this has been effected to the required extent, the mass is divided into small lumps, which are placed on shelves in a drying-room, and allowed to remain until fully desiccated. They are then reduced to powder, and placed on the shelves of a stove, the temperature of which is raised, on the first day to 100°; on the second to 150°; and on the third day to 190°. After this process, the powder is allowed to cool, and is then passed through a sieve. It is next placed in an oven, heated to from 300° to 350°, and when thoroughly baked it is ready for use.

The operator can ascertain if the process has been correctly carried out, by mixing a small quantity of the powder with filtered water, in which it should readily dissolve without leaving any sediment.

It will require little discrimination in the reader to see that this process, though there is some slight variation in the quantity and kind of acid, is yet essentially the same process with that of PAYEN given above.

If the flour or fecula be grey—that is, if it has been badly prepared, and adulterated or damaged—the patentee substitutes half a pint of sulphuric for the hydrochloric acid, by the agency of which, he states, the heterogeneous matters are separated from the good flour.

This patent also extends to the production of the gum in lumps, so as to resemble natural gum both in color and transparency; and for this purpose the powder is mixed, after it has gone through the stove and been sifted, with as much water as will bring it to the consistence of a paste, adding one part of nitric acid to each four hundred parts of water. When well mixed, the paste is spread upon copper dishes, in layers three-fourths of an inch deep, and subjected, in an oven, to a heat of 240° to 300°. As soon as it has become sufficiently hard, it is removed from the oven into the open air, and when cool, is ready for use.

Since the discovery, by PAYEN and PERSOZ, of diastase—described at page 71, Vol. I.—another method for the fabrication of artificial gum has been devised.

This process seems to be the most worthy of attention, and by accepting the modifications of M. EMILE THOMAS, it will be found to give more perfect results than any other. THOMAS' improvements with the original method of operation are thus described in the *Bulletin de la Société d'Encouragement*:—

The fecula must be rendered soluble in vats, heated by steam in such a manner that the temperature can be lowered or heightened with ease. The fecula is first mixed with four times its weight of water, previously brought to the temperature of 120°; and, for this purpose, is gradually introduced into the boiler or other vessel containing the hot water. M. THOMAS employed double-bottomed copper boilers, capable of containing four hundred gallons, and at one operation, six hundred pounds of fecula, mixed with one thousand

two hundred quarts of water were decomposed. The temperature must be kept at about 140°, until the whole mass is converted into starch. Two per cent. by weight of very fine white malt, and the mucilage obtainable from one per cent. of linseed, are then added. The latter imparts tenacity to the gum. If a greater proportion of malt than that just mentioned were employed, the decomposition would, doubtless, be effected more rapidly; but much more glucose would be formed, and the gum would be, to a greater or less extent, colored.

The temperature of the mixture must be maintained at 120° or 140° until all the starch is redissolved, when it should be suddenly elevated to 167°, as nearly as possible, in order to cause the most powerful action of which the diastase is capable. The thorough agitation of the mixture is then requisite, until the decomposition is almost complete; this may be ascertained by the deep blue tint which the mixture acquires, and also by the action of iodine, which will communicate to the dextrin a purple or violet tint.

The operation lasts about an hour and a quarter; fifteen minutes are required for the formation of the paste, the same period for its dissolution, and the remaining time for rendering it soluble.

M. THOMAS prefers this method of forming the paste to adding the malt, as the reagent spreads much more uniformly throughout the mass, and does not subside to the bottom of the vessel.

The liquor must now be removed from the decomposing vats, and left in pans to settle. This may require from six to eighteen hours, according to the external temperature. During this period, a slight fermentation will be perceived, but it must be checked by the addition of one hundred and forty-five grains of alum for each twenty-five gallons of the liquid. It is essential that sufficient time be allowed for subsidence of the menstruum, as by this means two serious evils are avoided—the coloring of the gum during the baking; and a singular phenomenon so often observed in evaporating viscous liquids, namely, their being quite *still*, which, THOMAS states, is caused by the accumulation of a thick crust on the sides of the evaporating vessels.

The liquor, when drawn off after subsiding, is concentrated by raising it *very slowly* to the boiling point, which precaution is indispensable, for the perfect clarification is effected without any foreign agent, by the coagulation of the vegetal albumen contained in the malt and the linseed mucilage, and is best attained by checking the first boiling. The scum which rises while the heat is maintained, must be carefully removed, and if the boiling is too much accelerated, the gum will first become thick, and afterwards will be colored. When a solid pellicle forms on the surface of the sirup, the baking will be completed.

If it be desirable to preserve the gum in a liquid form, the boiling must be stopped when the menstruum has acquired a sufficient density, and it must then be poured into well-closed vessels previously smeared with oil of turpentine, and the surface of the gum should be covered with a thin layer of the same. This method prevents, tolerably well, the fermentation of the fluid gum.

When the dextrin is to be solidified, the boiling sirup is poured into small, shallow tin vessels, placed upon a hot air stove, maintained at a temperature of from 100° to 120°. At the end of twenty-four hours the gum acquires the consistency of jujube paste, and it is then cut up, with a pair of shears, into small oblong pieces, which are rolled out upon a polished surface, with a wooden cylinder; dusted with pulverized artificial gum; and afterwards placed upon wooden frames, where it is allowed to remain drying for three or four days. THOMAS suggests that the gum would be much better desiccated by permitting it to run upon a cylinder heated to 230° or 250°, but he adds that the economy of this method is questionable.

The last-named authority has remarked with reference to British gum prepared by sulphuric acid, that it possesses the disadvantageous property of being deliquescent. This method is, therefore, never employed, as besides this, the products are often colored. He also states that when nitric acid is employed in the preparation of dextrin, *it must be perfectly pure*. Commercial nitric acid, as obtained by the action of oil of vitriol upon nitrate of soda, always contains a small amount of chlorine; and although this element is contained in diminished proportion in the dextrin, it is nevertheless sufficient to considerably lessen the brilliancy of the colors prepared with the dextrin. Several printers upon paper and vegetal tissues have observed this, but have been unable to account for it otherwise than by attributing it to the inferior quality of the gum.

GUM-BUTEA is the produce of the *Butea Frondosa*, a middling-sized tree, common in Bengal and the mountainous portions of India. Dr. PEREIRA found this gum to be identical with a substance he had previously obtained in the warehouse of an old drug firm in London, under the name of *gummi rubrum astringens*. It occurs, according to the last-named authority, in small, elongated tears, which are blackish externally, and have fragments of bark adhering to them. Small fragments examined by transmitted light are ruby-red. It has an astringent taste, and contains from fifteen to twenty-five per cent. of impurities, consisting of wood, bark, small pebbles, and sand. According to SOLLY, the gum, when purified by water, so as to separate the extraneous matters, is composed of—

	Centesimally.
Gum, with gallic acid and other soluble substances, ..	73.26
Tannic acid,	21.67
Soluble extractive,	5.07
	100.00

It is employed by the natives of North-western India for precipitating their indigo, and in tanning. English tanners, however, object to its use on account of the disagreeable color it communicates to the leather.

CHERRY-TREE GUM, *Gomme de cerisier*, French; *Kirschgummi*, German; *Gummi cerasi*, Latin; which is also procured from the trunks of plum, peach, apricot, and other rosaceous trees, is similar in appearance to the poorer qualities of gum-arabic. By the action of water, in which it is only soluble to a partial extent, it is divisible into two portions, that which is dissolved being *arabin*, while the insoluble matter is *cerasin*.

It has not been analysed, but its composition is probably the same with that of gum-arabic. Cherry-tree gum is not thrown down either by silicate of potassa or by nitrate of mercury. It does not gelatinise with sesquichloride of iron, but a precipitate is produced on the addition of chloride of tin.

It does not seem to have been employed for any purpose whatever in this country. Dr. PEREIRA has suggested its substitution for gum-tragacanth in medicine.

GUM-KINO.—*Gomme Kino*, French; *Gummi Kino*, German; *Gummi Kino*, Latin. Of this so-called gum there are two varieties, Botany Bay and East Indian kino, the former being the inspissated juice of the *Eucalyptus Resinifera*, or *Iron bark*, a native of Australia and Van Diemen's Land; while the latter kind is the produce of *Pterocarpus Erinaceus* or *P. Marsupium*. According to GRAY, when an incision is made in the trunk and branches of the tree, the juice exudes, at first, of an extremely pale-red color, and in a very liquid state; but it soon coagulates, becoming of a deep blood-red hue, and so remarkably brittle, that its collection is attended with some difficulty. East Indian kino, Dr. PEREIRA remarks, is presumed to be the substance referred to in the British pharmacopœias, as it is always regarded in commerce as *genuine gum-kino*. It is imported in boxes from Bombay or Tellicherry.

PROPERTIES.—East Indian kino occurs in small, angular, glistening fragments, the larger of which appear almost black; the smaller being ruddy. When entire, they are opaque, but in thin laminæ are transparent and ruby-red. They are brittle between the fingers, soften in the mouth, adhere to the teeth, tinge the saliva red, and, though inodorous, have a very astringent taste. Kino imparts both to alcohol and to water a deep-red color; the aqueous decoction, on cooling, becomes turbid. In the latter solution, gelatin, tartrate of antimony and potassa, acetate of lead, sesquichloride of iron, and nitrate of silver, produce precipitates.

Botany Bay kino is met with in irregular masses, many of them in the form of tears, somewhat resembling those of cherry-tree gum in outline, and as large as those of gum-senegal. The purer pieces are vitreous, almost black in the mass; but when in small and thin fragments, transparent, and of a beautiful ruby-red. Some of the pieces, however, from the intermixture of wood and other impurities, are dull. When chewed, it sticks to the teeth, and has an astringent taste, but is devoid of odor. Digested in cold water, it swells, becomes soft and gelatinous, and yields a red liquid, which gives an acid reaction with litmus paper, and yields precipitates with lime-water, gelatin, acetate of lead, sesquichloride of iron, and—if a little caustic potassa or ammonia be previously added—with chloride of calcium. Tartrate of antimony and potassa occasions no deposit. Digested in rectified spirit, Botany Bay kino becomes gelatinous, as with water, and affords a similar red solution, in which water causes no subsidence, but which reddens litmus, and deposits a copious precipitate when potassa, ammonia, or lime-water is added.—*Pereira*.

In 1852, Dr. CHRISTISON received from a merchant of Moulmein, a specimen of kino produced in that locality, possessing the physical and apparently the chemical properties of the ordinary kino. Though a small quantity of it was once shipped to England, it is yet, as an article of commerce, unknown.

The pharmacologist last named thus describes it:—

This product consists partly of little angular fragments; but there are larger masses which seem to be portions of cylinders, about half an inch in diameter, apparently moulded by collecting the juice in reeds. These have externally a greyish, striated surface, most unlike that of the broken fragments of commercial kino. They are easily frangible, the broken pieces possessing the exact appearance of ordinary kino, except that they are blacker and more glassy by reflected light; and though opaque, by transmitted light, when of very moderate thickness, yet in very thin fragments, they are of a splendid cherry-red color. They are easily reduced to fine powder, which has a dark, dirty, lake tint. Their taste is very slightly bitter, and intensely astringent.

Cold water acts more quickly on this kino than on that of commerce, gradually dissolving a very large proportion of it, forming a deep cherry-red astringent solution, and leaving a residue of greyish flocculent matter, which is soluble to a great extent in boiling water, and which appears to be analogous to the insoluble variety of gum called bassorin. Boiling water dissolves this kino almost entirely, and the menstruum, when cold, continues nearly transparent for at least an hour; it afterwards becomes slightly turbid, and a scanty flocculent precipitate slowly subsides. Both the hot and cold solutions yield, when much diluted, a deep olive-green precipitate with sesquichloride of iron; when the menstruum is concentrated, a dirty-grey precipitate is formed so abundantly, that the whole fluid becomes a thick, pulpy mass. A solution of one part of the kino in twenty-five of boiling water forms, with the iron-test, a magma too thick to flow. Even a solution in seventy-five parts of cold water has a beautiful intense cherry-red color, and forms with sesquichloride of iron, in the course of an hour, a pulp so thick as to flow only sluggishly.

On comparing these characters with a fine specimen of kino of home trade, and also with a sample from the neighborhood of Goomsoor, Dr. CHRISTISON found the last two to be identical, with the single exception, that the Goomsoor product is somewhat redder when seen in bulk, and that the Moulmein kino is blacker, more vitreous in lustre, rather more easily soluble in cold water, and with rather less residue; and when the cold solution is diluted to the strength of one in seventy-five, it requires rather more sesquichloride of iron to throw down all its tannin, and, consequently, the precipitate forms with the water a somewhat firmer pulp. This kino dissolves, with only a trace of flaky residue, in rectified spirit, which forms an intense cherry-red tincture of very pure astringent taste. Its physical characters, the action of water, and the properties of the aqueous solution, are enough to prove that the Moulmein kino is identical with the kino of commerce, and, in point of quality, is somewhat superior. There is no

doubt, from its taste, and the action of the iron-test, that analysis will prove the presence of a larger proportion of tannin.

It does not absolutely follow, even from the exact coincidences now mentioned, that the Moulmein kino is derived from the same botanical source with the present official kino. The latter has been accurately referred, by the separate researches of GIBSON, PEREIRA, and ROYLE, to the *Pterocarpus marsupium* of ROXBURGH. But the *Butea frondosa* also yields a fine kino, which is scarcely distinguishable in chemical properties from the official kind.—*Pharmaceutical Journal*.

COMPOSITION.—Gum-kino was first analysed by VAUQUELIN, in whose days the resources of chemistry were very much limited, causing a deviation from the truth in many cases, and occasioning, with regard to all investigations of the period, a great amount of doubt as to their correctness.

The comparatively simple tabulation of VAUQUELIN'S results is as under:—

	Centesimally.
Tannic acid and peculiar extractive,	75
Red gum,	24
Insoluble matter,	1
	100

The presence of catechuic acid has subsequently been proved by A. W. BUCHNER.

USES.—For medical purposes only; it is administered in cases of obstinate diarrhoea; it has occasionally been applied to flabby ulcers as a local astringent.

STATISTICS.—Gum-kino is imported from Rangoon and Madagascar into London and Liverpool, in chests and boxes containing each from one to three hundred-weight. It varies in value from fifty to seventy shillings per hundredweight. Duty-free.

GUM-KUTEERA bears considerable resemblance to flaky tragacanth, for which it has occasionally been attempted to be substituted. GUIBOUT considered it as identical with gum-bassora, but PEREIRA states that it is very distinct. It is supposed to be produced by the *Sterculia Urens*, a plant of the family *Byttneriaceae*, and is unknown in British commerce.

GUM-MEZGNITE, known synonymously as *muckeet*, *mezgneet*, or *musgnit*, has been described by MORFIT, who was led to submit it to a chemical examination, on account of the facility with which it may be obtained in large quantities, and its very probable prospective value as an article of commerce.

It is said to be the product of a tree flourishing extensively in the high and dry regions of the plains of Western Texas, New Mexico, and the adjacent Indian territory. It is a spontaneous semifluid exudation, concreting by exposure into tears and lumps of variable size and form. A portion of the sample obtained by Dr. SHUMARD—who first brought it into public notice in 1854—consisted of small irregular pieces and rounded balls about the size of a hazel-nut; semi-transparent, and shading in color from a lemon-white to a dark amber. When broken, the fractured surfaces were brilliant, and the gum was easily reduced to a dull white powder. One of the balls was enveloped with an outer pellicle of gum, about one-sixteenth of

an inch in thickness. Its specific gravity was 1.5, but MORFIT remarks that this determination may admit of correction upon purer samples than were obtainable.

Its proximate composition was found to be:—

	Centesimally.
Arabin,	84.967
Bassorin,	0.206
Water,	11.640
Inorganic matter,	3.000
Impurities,	0.236
	100.049

Its elementary composition is represented by MORFIT as—

	Centesimally.
Carbon,	44.706
Hydrogen,	6.500
Oxygen,	48.794
	100.000

which approaches very closely to that of gums arabic and senegal, as represented by GUERIN and MULDER. The general appearance of the gum, continues its describer, is similar to that of gum-senegal and the dark inferior qualities of gum-arabic; while in chemical properties it is also allied to them, being insoluble in absolute alcohol, partially soluble in alcohol of the ordinary strength, and readily forming with hot or cold water a very adhesive mucilage. It is, in fine, a true gum, and promises, in its physical and chemical behavior, much of the advantage expected by its discoverer, as an economical substitute for gum-arabic or senegal.

MUCILAGE.—*Mucilage*, French; *Schleim*, German; *Mucilago*, Latin.—Many seeds, roots, &c. *cetera*, when infused in water heated to 160° or 170°, impart to it a substance, which, when purified by percolation and evaporation, bears considerable resemblance to gum.

QUINCE MUCILAGE.—One part of quince seed, Dr. PEREIRA states, forms, with forty parts of water, a thick mucilage, which yields with acetate and subacetate of lead, protochloride of tin, nitrate of mercury, and sesquichloride of iron, gelatinous coagula or precipitates. Rectified spirit produces at first scarcely any effect; after some time partial concretion occurs. Sulphuric acid communicates a pinkish tint, and causes the separation of a frothy coagulum, which floats on the mixture. Silicate of potassa, infusion of galls, and oxalate of ammonia produce no change in the mucilage. Quince mucilage is distinguished from arabin, by the effect on it of alcohol, silicate of potassa, oxalate of ammonia, and sulphuric acid; from bassorin and cerasin by its solubility, both in cold and hot water; from tragacanthin, by the reactions caused by alcohol, oxalate of ammonia, and sulphate of iron; from *carrageenin*—see carrageen mucilage below—by the effect of silicate of potassa and acetate of lead. From these and other peculiarities, Dr. PEREIRA proposed to call it *cydonin*—derived from the name of the quince-tree, *Cydonia Vulgaris*.

CARRAGEEN MUCILAGE.—The mucilaginous constituent of Carrageen or Irish moss—*chondrus crispus*—termed by some writers vegetal jelly, or vegetal mucilage, was, from its appearing to have peculiar characteristics, designated by Dr. PEREIRA *carrageenin*. Its

properties, according to that distinguished pharmacologist, are as follow :—

Carrageenin is soluble in boiling water; the menstrum gives precipitates with subacetate of lead and silicate of potassa, and, if sufficiently concentrated, gelatinizes on cooling. It is distinguished from ordinary gum by its aqueous solution not producing a precipitate on the addition of alcohol; from starch by its not assuming a blue color on the addition of iodine; from animal jelly by tincture of galls producing no precipitate; from pectin by the absence of any reaction with acetate of lead, as also by the formation of no mucic acid on the addition of nitric acid.—*Pereira's Materia Medica.*

LINSEED MUCILAGE is extracted from the seeds of the flax-plant, *Linum Usitatissimum*, by the agency of hot water. Alcohol causes the formation in it of white mucilaginous flocks. It is also precipitated by protochloride of tin, and by acetate and subacetate of lead. It possesses an acid reaction, and is not changed by chlorine or iodine. On evaporation, a substance similar in appearance to gum-arabic is obtained, which, when digested in water, intumescs, and partially dissolves.

There are many other mucilages, but as they possess characters in common with those described, a notice of them would be unwarrantable.

GUM-TRAGACANTH, or *Gum-dragon*—*Gomme tragacante*, French; *Gummi tragant*, German; *Gummi tragacantha*, Latin—is a natural exudation from different varieties of the *Astragalus*, or milk-vetch. OLIVIER states that the tragacanth of Asia Minor, Armenia, and northern Persia, is yielded by the *A. Versus*. Mr. BRANT, English consul at Erzeroum, forwarded to Dr. LINDLEY a specimen of *A. Gummiifer*, which was stated to be the tragacanth plant of Koordistan, and producing the white or best kind of gum. It was accompanied with a plant of *A. Strobiliferus*, which was said by the same authority to be the shrub from which the red or inferior species of tragacanth is produced.

According to TOURNEFORT, the *Astragalus Creticus* also yields the gum.

DESCRIPTION.—Gum-tragacanth is white, yellowish, or yellowish-brown, and occurs either in moderately large, broad, thin pieces, marked with arched or concentric elevations—*flaky tragacanth*,—or in small, twisted, filiform, spiral fragments—*vermiform tragacanth*. The former is the kind usually found in this country, while the latter is common on the Continent.

COLLECTION AND ASSORTMENT.—According to S. H. MALTASS, the following is the manner in which gum-tragacanth is collected :—In July and August the peasants clear away the earth from the lower part of the shrub, and make several longitudinal incisions in the bark; the gum exudes the whole length of the incision, and dries in flakes; three or four days are sufficient for this purpose, and the product is then collected. In some places the peasants also puncture the bark with the point of the knife. If the weather be hot and dry, the gum is white and clean; but if the atmosphere be damp, and the temperature but moderate, a longer time is required for inspissation, and the gum assumes a yellow or brownish tinge.

High winds are favorable for drying, but they cause the contamination of the gum with earthy and silicious matters. While engaged in this labor, the peasants pick off from the shrubs the gum which exudes naturally, and this constitutes the variety known in Britain as *common* or *sorts*. The whole of the tragacanth gathered is mixed and sold to native merchants, who send it to Smyrna for re-sale, in bags containing about two hundredweight each. In this state it is termed *rough gum*, and contains as follows :—

	Per Cent.
Flaky or leaf gum, perfectly white, . . .	40 to 50
Flaky or leaf gum, discolored or brown, . . .	15 to 25
Vermicelli gum,	10 to 15
Common or sorts,	35 to 10

The finest parcels, continues this authority, contain the most *vermicelli*, which is nothing more than the siftings of the *leaf* gum which is broken by carriage from the interior, and by removing from one place to another, together with the small vermicular masses termed *Sesame seed*, which are collected with the leaf gum.

When gum-tragacanth is purchased for shipment to Europe, it undergoes the following assortment :—The large, white, flaky, or leaf gum, termed *French quality*, is first picked out, and the residue is sifted. The coarser portion is returned to the pickers, who remove the *discolored leaf*, which is termed *English quality*. The remainder is then examined, and any stones, or dirty, very black pieces are thrown aside as refuse; the rest, composed of naturally exuded gum and brown leaf, is denominated *common* or *sorts*.

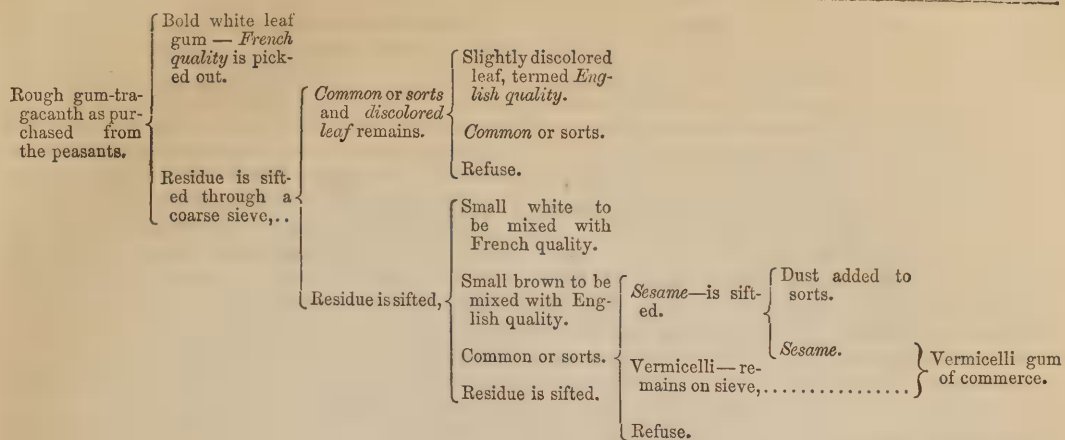

The head-man or master-picker then subjects the gum which passed through the first sieve, to the action of a second and finer one, occasionally throwing out any straw or other light extraneous substance which may rest at the top. The gum remaining after this second sifting is given to the women to assort at their own houses. The *white* is separated from the *brown*, and the latter from the *common*. The first is mixed with the French, the second with the English quality.

A third, and still finer sifting now takes place. The gum which passes through is termed *Sesame seed*; the coarse, which remains upon the sieve, is *vermicelli*. Both qualities are carefully picked by women. When cleaned, the *Sesame seed* is again sifted, and the dust and minute particles are added to the *sorts* or *common* gum. The *Vermicelli* and *Sesame seed* are then commingled, forming the *vermicelli tragacanth* of commerce.

When the gums are intended for the French market, the fine white leaf only is shipped; the *vermicelli* is sold for Trieste, and the discolored leaf and *sorts* for England.

If, however, the whole parcel be worked for Britain, and be required *good*, the French and English qualities are mixed, and the brown leaf which had been left in the *sorts* is also picked out and added. This procedure reduces the value of the *common* or *sorts*.

The various siftings and pickings to which gum-tragacanth is subjected at Smyrna, may be thus tabulated :—

—*Pharmaceutical Journal*.

PROPERTIES AND COMPOSITION.—Gum-tragacanth is the type of the *Bassorin* class of gums. It is destitute both of taste and odor. Its toughness is so great as to prevent its pulverization until it has been exsiccated at 212°, when it becomes tolerably brittle. Instead of dissolving in water like gum-arabic, it intumesces, forming a mucilaginous magma. On subjecting this to ebullition with water, it gradually acquires the appearance of a solution of gum-arabic, in consequence, *BRANDE* supposes, of its transmutation into arabin.

The soluble portion of gum-tragacanth—tragacanthin or adragantin—is generally regarded as identical with gum-arabic, but differs from it in being unchanged by sesquichloride of iron, or silicate of potassa, and also by the flocculency of the precipitate occasioned by alcohol. Subacetate of lead, protochloride of tin, and protonitrate of mercury, produce deposits similar to those caused in a solution of gum-arabic. The presence of lime is shown by the subsidence occasioned by oxalate of ammonia.

The insoluble part of gum-tragacanth—*bassorin*—is similar to that of gum-bassora. Starch globules may be seen in it, with the aid of a good microscope, and the blue coloration produced in it by iodine is a proof of the presence in it of that principle.

DE CANDOLLE has suggested that the intumescence of tragacanth may be caused by the gummy matter being enclosed in cells.

GUIBOUT states that neither arabin nor bassorin are present in gum-tragacanth, but that it is composed of an organised gelatiniform matter, very diverse, both chemically and physically, from gum-arabic, and which swells and divides in water, so as partially to traverse a filter. The same chemist considers the insoluble portion of tragacanth to be a compound of starch and lignin, and to have, in no respect, the same properties with bassorin.

GUERIN-VARRY estimated the proximate principles of tragacanth as under:—

	Centesimally.
Tragacanthin or arabin,.....	53.3
Bassorin and starch,.....	33.1
Water,.....	11.1
Inorganic matter,.....	2.5
	100.0

The ultimate constituents of gum-tragacanth have been determined by *HERMANN*, and by *GUERIN-VARRY*:—

	At. weight.	Centesimally represented.	
		Theory.	Hermann.
10 Eqs. Carbon,.....	60	40.00	40.50
10 Eqs. Hydrogen,.....	10	6.66	6.61
10 Eqs. Oxygen,.....	80	53.34	52.89
1 Eq. Gum-tragacanth, 150		100.00	100.00

GUERIN-VARRY's results are as follow:—

	Centesimally.	
	Soluble part.	Insoluble part.
Carbon,.....	42.01	35.79
Hydrogen,.....	6.42	7.11
Oxygen,.....	54.47	57.10
	102.90	100.00

USES.—Gum-tragacanth is occasionally employed in medicine as a sheathing or demulcent agent in irritation of the mucous membranes; and also as a vehicle for the administration of active and heavy medicines.

Shoemakers use the inferior varieties, in the form of mucilage, for imparting a gloss to the heels of boots.

ADULTERATION.—According to *S. H. MALTASS*, gum-tragacanth is adulterated with two inferior gums. These, he says, are collected in Armenia and Caramania from various trees, principally wild almond and plum. That from the former locality is sent to Constantinople from Moussul, whence it takes the name of *Moussouli*. The Caramanian product is sent direct to Smyrna, and is termed *Caraman*.

Both these gums, continues he, are almost worthless, but fetch high prices for the purpose of mixing with gum-tragacanth. By some they are considered to be an inferior kind of the same gum. As neither Caramania nor Moussul gum occurs in flat pieces like tragacanth, and as they are of a dark color—particularly the former—they would be easily detected if mixed with leaf gum without previous preparation. The Jews, therefore, who adulterate all the drugs of Turkey, have found means of deceiving the eye by breaking up the spurious article into small irregular pieces, which are then coated with *white-lead*. The leaf gum is sophisticated with this at the rate of fifty

per cent. For mixing with the Vermicelli gum, the adulterant is broken into smaller fragments, and added only to the extent of twenty-five to thirty per cent. The pieces are left largest for the sorts or common gum, which often receives even a hundred per cent. of this vile trash.—*Pharmaceutical Journal*.

When pulverized, gum-tragacanth is very often mixed with a multitude of other cheaper powders, more especially with gum-senegal.

A mixture of gums tragacanth and senegal always forms with water a thinner mucilage than the same quantity of either of them alone. The following process is indicated by PLANCHE for the detection of this fraud:—Make a mucilage of the suspected gum, and add to it a few drops of alcoholic tincture of guaiacum, taking care to agitate the menstruum all the while. If the gum under examination contain any gum-arabic, the mixture, in the course of a few minutes, assumes a fine blue color, whilst if the gum-tragacanth be pure, the tint is unaltered. One-twentieth of gum-arabic can thus be detected. It should be remarked, that only

four or five drops of tincture of guaiacum should be employed for two drachms of mucilage, and that when the quantity of gum-arabic is very small, three or four hours must often elapse before the change of color can be observed. When rectified alcohol is poured in a clear and filtered mucilage of gum-tragacanth, it produces only a few flakes, which float in the menstruum, but do not impair its transparency; whilst, if gum-arabic be present, either a precipitate occurs in the liquid, or it becomes opalescent, according to the proportion of gum-arabic which it contains.—*Normandy*.

STATISTICS.—Gum-tragacanth is imported in cases of one hundredweight each into London and Liverpool. Its value, picked, is from ten to fourteen pounds sterling per hundredweight; sorts, from four to eight shillings per pound. Duty-free.—*Poole*.

Subjoined are particulars of the imports and exports of gums—Arabic, Senegal, Kino, and Tragacanth, those being the only gums noticed in the Returns of the Board of Trade—during the years mentioned:—

GUM-RESINS.—*Gommes-résines*, French; *Schleimharze*, German; *Gummi-resina*, Latin.—This class of vegetal products has long been recognised in pharmacy, and the various substances forming it certainly possess a sufficient number of peculiar properties to entitle them to be ranked apart. Their nature is not expressed by the term *gum-resin*, and the designation has consequently been condemned as improper; but it has been long sanctioned by use, and seems likely to be retained. They are the inspissated juices which exude either spontaneously, or by means of incisions, from the stems, branches, and roots of certain plants; and consist of resin, gum, essential oil, with other vegetal substances, as starch, and a small amount of inorganic matter. Their general properties are, that they are solid, most commonly brittle, usually opaque, or at least their translucence is not so great as that of the resins; they have almost always a strong smell, and often an acrid taste. Water partially dissolves them, but the resulting menstruum is opaque, and in general, lacteous. Alcohol takes up a portion of them, forming a transparent solution, which is rendered milky by the addition of water. They are principally used in medicine, having little application in the arts and manufactures.

AMMONIAC.—*Gomme Ammoniaque*, French; *Ammoniak-gummi*, German; *Ammoniacum*, Latin.—This substance is the product of the *Dorema Ammoniacum*,

a glaucous green plant, about seven feet high, the stem being about four inches in circumference at the base; a native of Persia. The whole plant, according to PEREIRA, is abundantly pervaded with a milky juice, which exudes upon the slightest puncture being made even at the ends of the leaves. This sap, when hardened, is the commercial ammoniac or ammoniacum of the present day.

The last-named authority states that this term has also been applied to a gum-resin, the produce of the *Ferula Tingitana*, which constitutes the ammoniacum of HIPPOCRATES, DIOSCORIDES, and PLINY. The second of these writers says, that ammoniacum is obtained from a species of *Ferula*, growing near Cyrene, in Africa. PLINY terms the plant *Metopion*, and states that it grows in that part of Africa which is subject to Ethiopia, near the temple of JUPITER AMMON, and received its name, as also did the gum-resin which it produced, from a Greek word signifying *sand*, in allusion to the arenaceous nature of the soil of the country. Two kinds of ammoniac are mentioned both by DIOSCORIDES and PLINY; the best resembled olibanum, and had a bitter taste, and an odor like castoreum; the commonest had a resinous appearance, and was commingled with earth and stones. DR. LINDLEY assured DR. PEREIRA, that African ammoniac was certainly the produce of *Ferula Tingitana*.

As the Greeks and Romans made no mention of

Persian ammoniac, the product of the *Dorema Ammoniacum*, they were, probably, unacquainted with it. AVICENNA notices ammoniac, but says nothing of its origin. That of ABU MANSUR MOWAFIK, a Persian physician who wrote about A.D. 1055, and of BEVA BEN KHUAS KHAN, A.D. 1512, was, doubtless, of the Persian kind. The Arabic terms by which the three last-mentioned authors designate ammoniac, resemble the name by which the plant is now known in Persia; hence it may be concluded that they all referred to the same object.—*Pereira*.

DESCRIPTION AND PROPERTIES.—Ammoniac is found in tears and drops, sometimes distinct, but more generally in agglutinated masses. Externally the tears are yellow, with a tinge of brown, with a waxy lustre; internally they are white or cream-colored, and opaque. It is moderately hard, and at ordinary temperatures brittle, but softens like wax with the heat of the hand. It has a faint and somewhat unpleasant, but very peculiar odor, best detected by subjecting it to heat; its taste is bitter and nauseous.

M. PICARD, in 1852, discovered by accident a very characteristic reaction of chloroxide of sodium—usually known as hypochlorite of soda—upon gum-ammoniacum. The addition of a few drops of a solution of the former to an alcoholic menstruum containing ammoniacum dissolved, causes the immediate development of a very distinct coloration. As this chemist was operating at the time with the commercial alkaline salt, which consists not only of chloroxide, but also of chloride of sodium and carbonate of soda, he thought it proper to inquire which of these compounds caused the reaction, and he soon found that it was due wholly to the chloroxide. Another question presented itself:—Is it the resinous or the gummy part of the ammoniacum which acts in this phenomenon? To find an answer to this, he attempted the complete separation of the two principles by the following method:—An alcoholic solution of ammoniacum, evaporated to the consistence of a sirup, was precipitated by distilled water. The resulting resin, well edulcorated, was redissolved in alcohol, evaporated, and reprecipitated. This treatment was repeated until nothing more was removed by the water, when the resin might be considered as pure. Its alcoholic solution behaved with chloroxide of sodium, like the gum-resin from which it was derived.

The evaporated menstruum obtained in isolating the resin was treated with alcohol, which precipitated the gum, and this manipulation was successively repeated until the gum, which had a brownish cast, dissolved easily and completely in water. This menstruum giving no reaction whatever with the chloroxide, warranted PICARD in asserting that the coloration was due exclusively to the resin. To attain to more precision, he acted on the method prescribed by PELLETIER and BONASTRE for the separation of the resins, which, since their researches, have been termed *resins* and *sub-resins*, according to their solubility in ether; and found that the ethereal solution, which was of a fine amber tint, at once gave the reaction with the alkaline chloroxide; while the small blackish globule of insoluble matter, when affused with ether and dis-

solved in alcohol, was unaltered by the reagent in question.

The sensibility of the reaction of chloroxide of sodium upon ammoniacum is very intense; a mere trace of the former in a menstruum containing the latter is sufficient to produce the phenomenon. This coloration, however, is not persistent; it disappears in contact with the air. If but little chloroxide has produced the reaction, it will reappear on a further addition; but if the reagent be in excess, the presence of another quantity will not induce a return of the tint. A large excess of chloroxide causes it to vanish, especially with the addition of an acid which disengages chlorine. To study the reaction satisfactorily, PICARD proposes three questions:—

1. Of all the resins and gum-resins, is ammoniacum the only one which thus comports itself with chloroxide of sodium, so that this reaction would serve as a distinctive characteristic of it?

2. Is this reaction peculiar to the chloroxides, and have the oxidising agents which most nearly resemble them no analogous result?

3. Is it possible by means of this reagent to detect gum ammoniacum in a pharmaceutical preparation, when it is mixed with other substances?

There are so many characters, continues the distinguished French pharmacologist, common to all resins, that gum-ammoniacum could scarcely be expected to possess exclusively the property of being influenced by chloroxide of sodium. If the resin of guaiacum, however, be excepted, which gives with this reagent a bluish-green coloration, none were influenced. The principles furnished by vegetals of the same family offer a remarkable analogy of chemical and therapeutical properties. Galbanum, sagapenum, opoponax, asafetida, furnished by the *Umbellifere*, a natural family from one of the species of which gum-ammoniacum proceeds, have, however, shown no change when treated with chloroxide of sodium. It is the same with myrrh, olibanum, mastic, sandarac, resins of jalap, scammony and elemi, liquid and calamite storax, benzoin, balsam of tolu, dragon's blood, euphorbium, colophony, resin pitch, white pitch, and turpentine. A distinctive characteristic of gum-ammoniacum is, therefore, its property of assuming a red color with chloroxide of sodium. It should, however, be mentioned that these experiments were made with the alcoholic tinctures, and not with the isolated resins.

The chloroxides of potassium and calcium have the property, in common with that of sodium, of developing the tint; but chlorine does not possess it. If a little carbonate of soda is previously added to chlorine water, the coloration is readily effected, in consequence of the formation of a small amount of chloroxide. Chloric, iodic, chromic, nitrous and nitric acids, and sesquichloride of iron, offer nothing remarkable.

In these investigations, the very powerful vinous color communicated to aloes by the alkalies must be borne in mind. Chloroxide of sodium from its alkalinity, reacts in a similar manner.—*The Chemist*.

A specimen of African ammoniac sent from Tangiers in 1839, is thus described by Dr. PEREIRA, to whom it was presented by Dr. LINDLEY:—It is an oblong

piece, about three inches long, and one and a half inch thick and broad. Its weight is about eight hundred and thirty grains. Externally it is irregular and uneven, and has a dirty appearance, similar to that which ammoniac would present after repeated handling and long exposure to the air in a dusty situation. It is partially covered with paper. A few pieces of reddish chalky earth, effervescing with acids, are found adhering to it, though the proportion of this on the specimen in question is not sufficient to affect in any way its saleability. It appears to be made up like Persian ammoniac, of agglutinated tears; the internal appearance is also much the same as that of the ordinary gum-resin, except that it is not so white, having a brownish, reddish, and in some places a faint bluish hue. Its odor is very faint, and when it is heated, obviously very distinct from that of Persian ammoniac. Its taste is also much slighter.

COMPOSITION.—Ammoniacum has been analysed by several chemists, with various results. BRACONNOT found it to yield the following:—

	Centesimally.
Resin,	70.0
Gum,	18.4
Gluteniform matter, insoluble in water and alcohol,	4.4
Water,	6.0
Loss,	1.2
	100.0

HAGEN's analysis gave:—

	Centesimally.
Resin,	68.6
Gum,	19.3
Gluten,	5.4
Extractive,	1.6
Silicious matter,	2.3
Volatile oil and water,	2.8
	100.0

But these statements of the composition of ammoniacum, from the limited means of analysing organic substances at the time they were deduced, are very unsatisfactory; and there is no doubt that an investigation of the subject, now that organic chemistry has become so fully developed, would show their erroneousess. Of the volatile oil of ammoniacum, little, indeed nothing, is known; Dr. PEREIRA giving as a description of it, the simple statement that *it is transparent and lighter than water*.

JOHNSTON obtained the resin of ammoniacum by digesting the gum-resin in alcohol, whereby he obtained a pale yellow solution, which, on evaporation at 150°, gave a transparent, nearly colorless resin, having the characteristic odor of the natural product. This resin is soluble in alcohol and the alkalis; partially so in ether, and in fixed and volatile oils. Heated to 212° for some time, it assumes a yellow color, which gradually deepens, while at the same time the peculiar odor becomes less intense. It is easily fusible, and decomposes at a continued heat of 270°; the volatile matter which is evolved containing more oxygen in proportion to the hydrogen than exists in the resin itself. JOHNSTON has expressed its composition, after slow but complete desiccation, by the formula, $C_{40}H_{25}O_9$.

USES.—Ammoniacum is principally employed in medicine; internally, its chief, almost sole use, is in chronic pulmonary affections, and even in these cases, it is unsuitable if there be irritation or inflammation of the bronchial membrane. Externally, it is applied in the form of plaster to glandular enlargements and indolent affections of the joints, as a discutient or resolvent.—*Pereira*.

Its only use in the arts, says URE, is in the formation of a cement for joining broken china and glass, and which is prepared as follows:—Take isinglass, one ounce; distilled water, six ounces; boil these together down to three ounces; add half that quantity of strong alcohol, seethe the mixture for two or three minutes, and then strain it; next add, while hot, first, half an ounce of milky emulsion of ammoniacum, and then five drachms of an alcoholic solution of resin mastic. This resembles an article sold as *diamond cement*.

ASAFETIDA—*Assa fetida*, French; *Asafetida*, *Teufelsdrück*, German; *Asafetida*, Latin—is obtained from the *Ferula Asafetida*, an umbelliferous plant found in Afghanistan, Saristan, and the Punjab. The footstalks of the leaves, and the fibres of the root, being previously removed, incisions are made in the latter, and the gum-resin then exudes, and is removed. This procedure commences about the middle of April, and is repeated towards the latter end of May, and the beginning of June and July in each year.

According to Dr. PEREIRA, the root of the *Ferula Asafetida* is perennial, tapering, ponderous, increasing to the size of a man's arm or leg, covered with a blackish-colored bark, and beset near the top with many strong rigid fibres; its internal substance is white, fleshy, abounding with a thick milky juice, which has an excessively strong, fetid, alliaceous odor. The stem is two or three yards high, six or seven inches in circumference at the base, and smooth. The radical leaves attain the length of nearly two feet, and have been compared by KÆMPFER as resembling in shape those of the pæony, but in color and other respects those of common lovage. The fruit is flat, thin, reddish-brown, like that of parsnip, but rather larger and darker.

This is now considered, continues the last-named authority, to be the genuine asafetida plant; but there is reason to believe that a gum-resin like asafetida has been procured from other species of ferula. *Ferula Persica* has been described by Dr. POPE as the true asafetida plant, and the Edinburgh College of Physicians admitted it as being probably one source of the gum-resin. That it really does yield asafetida seems likely, moreover, from the strong odor of the drug which pervades the entire plant.—*Pereira*.

HISTORICAL NOTICE.—For the historical notice of asafetida, the Editor is also indebted to Dr. PEREIRA, who has collected from many sources the following:—It is uncertain at what period asafetida was first known or described. The difficulty in determining its history arises from the confusion which has existed with respect to the *Succus Cyrenaiacus* and asafetida. By many writers the two substances were considered to be identical; but this opinion seems now to have been satisfactorily disproved by the discovery of the plant

which yields the Cyrenaic juice, and which agrees tolerably well with the rude figures struck on the Cyrenian coins. It would appear, however, that the Cyrenaic juice becoming scarce, the ancients employed some other substance of similar, though inferior, properties as a substitute, and to both of these they applied the term *laser*. For many years, says PLINY, this plant has not been found in Cyrenaica, because the publicans—or farmers of the taxes—who rent the pastures, finding it more profitable, destroy it as food for cattle. One stalk only, found in these days, was sent to the Emperor NERO. It may be known when cattle meet with young shoots of it, by the sleeping of the sheep, and the sneezing of the goats, when they have eaten of it. For a long time past the only laser brought is that which is produced abundantly in Persia, Media, and America, but it is far inferior to the Cyrenaic. It is not at all improbable, continues Dr. PEREIRA, that the laser of Persia may have been the asafetida of the present day. MURRAY says the word *asafetida* seems to have been introduced by the monks into the school of Salerno. But it appears to have been of oriental origin, and may be, as some have suspected, derived from the word *laser*. There are two kinds of *assa*, says AVICENNA, one *fetid*, the other *odoriferous*.—*Materia Medica*.

DESCRIPTION.—Asafetida is found in irregular yellowish or pinkish-brown fragments, of different sizes. The newly-fractured surface is whitish or cream-colored, semi-transparent, and possesses a waxy lustre; but on being subjected for a few hours to the combined influence of air and light, it becomes violet-red, and after the lapse of some days, yellowish or pinkish-brown. Dr. PEREIRA has described three varieties:—

1. *Asafetida in the tear*, which occurs in distinct, roundish, flattened, or oval drops, and also in irregular pieces, varying from the size of a pea to that of a walnut, of a yellow or brownish-yellow externally, but white internally. It is not at all improbable that this variety is obtained from a source different from that whence the lump asafetida is procured; for its color, externally, is more yellow, its odor is much feebler, and its freshly-fractured surface becomes more slowly and less intensely red by exposure to the atmosphere. As it has considerable resemblance to *ammoniacum in the tear*—with which, indeed, except by its odor, it might readily be confounded—may it not be the substance which OLIVIER calls ammoniacum, and which, he says, is produced by *Ferula Persica*?

2. *Lump asafetida*, which is the variety usually found in the shops. It occurs in variable-sized masses, of irregular forms, and having a reddish or brownish-yellow tinge. Frequently these masses are observed to be made up of tears, agglutinated by a reddish-brown substance; these form that kind of asafetida sometimes designated *amygdaloid*.

3. *Stony asafetida*. Dr. PEREIRA never met with this in English commerce, but has described samples which he received from Dr. MARTINY: It occurs in irregular, more or less angular, pieces, which have the odor of asafetida, and a yellowish-brown color, and present numerous small shining points or plates. It slightly effervesces in hydrochloric acid. By incine-

ration it yields a white ash, which strongly effervesces on the addition of acids. ANGELINI found in stony asafetida 51.9 per cent. of sulphate of lime.—Dr. Pereira.

PROPERTIES AND COMPOSITION.—Asafetida is very easily known by its peculiar alliaceous odor. This is the more readily appreciable when the gum-resin is subjected to heat. Exposed to light and air, its recently broken surface soon acquires a red color, which gradually passes into yellowish or pinkish-brown. Its taste is acrid and bitter. With sulphuric acid and heat it blackens; a dark, blood-red fluid is produced, and sulphurous acid is evolved. On diluting the menstruum, and adding an excess of caustic potassa, a beautiful blue color may be seen by reflected light, more especially on the surface.

Asafetida consists principally of resin, gum, and volatile oil. BRANDES analysed it with the following results:—

	Centesimaly.
Resin,.....	48.5
Gum, with traces of saline matters,.....	19.0
Bassorin,.....	6.4
Volatile oil,.....	4.5
Extractive, with saline matters,.....	1.4
Sulphate and carbonate of lime,.....	9.3
Oxide of iron and alumina,.....	0.4
Sand and lignin,.....	4.5
Water,.....	6.0
	100.0

The volatile oil of asafetida is prepared by distillation, either with water or alcohol, and passes over colorless, though by a brief exposure to the atmosphere it becomes yellow. It possesses first a mild, and subsequently a bitter taste; its odor is remarkably powerful, and as it is very volatile, the atmosphere of any apartment where it may be exposed is soon impregnated with it. It is very soluble in alcohol and ether, but two thousand times its weight of water are required to dissolve it. It contains sulphur, which may be known by its blackening silver, and Dr. PEREIRA thinks it probable that phosphorus is likewise present. According to some, the oil is composed of two sulphides of the hydrocarbon, $C_{12}H_{11}$, and when freshly distilled, like the essential oils of black mustard and horseradish, it contains no oxygen. It acquires an acid reaction from continued contact with the air, and on boiling it, sulphide of hydrogen is disengaged.

The resinous matter of asafetida may be isolated by digesting the gum-resin in alcohol, and evaporating the solution; by this simple process, however, it cannot be considered as pure, and it is better obtained in this state by adopting the method described by M. PICARD for the preparation of the resin of ammoniacum, and given at page 321. It is soluble in alcohol, oil of turpentine, and oil of almonds. It has the characteristic odor of the gum-resin, and the property which the natural product possesses of becoming violet-red by exposure to the sun's rays. BRANDES states that ether divides it into two portions, resin and sub-resin, which he has described; but JOHNSTON affirms that it is *readily and completely soluble in ether*. Like many other resins, it must be heated for a length of time before it becomes hard and brittle, and reaches its normal condition.

By this prolonged heating, it acquires a darker and brownish color, and is easily decomposed if the heat be carried much beyond 212° . As the temperature rises, the resin froths up very much for some time, giving off a strong alliaceous odor; it then flows quietly till the heat is again increased.

Its elementary composition, according to JOHNSTON, is represented by the formula, $C_{40}H_{26}O_{10}$, which differs from that of the resin of ammoniacum in containing the elements of an additional equivalent of water.

USES.—In Europe solely as a medical agent; it is found highly useful in spasmodic or convulsive diseases not dependent on the nervous centres; as a stimulating expectorant and antispasmodic in chronic catarrh; in affections of the alimentary canal; as an emmenagogue in uterine obstructions. In some oriental nations, as mentioned in the historical notice of asafoetida, it is employed as a condiment.

BDELLIUM.—By this term two gum-resins are understood; one, obtained from *Amyris Commiphora*, the bdellium of Holy Writ, known as *Indian bdellium*, or *false myrrh*; the other, derived from *Heudolatia Africana*, is called *African bdellium*. It is called by the natives, *niottout*. It occurs in commerce in translucent tears, often of considerable size. These vary in tint, some of them being of a brown color, more or less dark. By age they become opaque, and covered with a white or yellowish dust. Their fracture is dull and ceriferous. Bdellium has a feeble, peculiar odor, and a bitter taste. PELLETIER states that it consists of—

	Centesimally.
Resin,	59.0
Soluble gum,	9.2
Bassorin,	30.6
Volatile oil and loss,	1.2
	100.0

JOHNSTON represents the composition of the *resin* of bdellium, by the formula $C_{40}H_{31}O_5$, or $C_{60}H_{62}O_{10}$.

EUPHORBIIUM is the produce of different species of *euphorbia*, a plant growing in the interior of Africa. It exudes in the form of a milky juice, so acrid as to excoriate the fingers, and which hardens by the heat of the sun into irregular yellowish tears. It is nearly inodorous, but its dust excites incessant sneezing. Its taste, at first slight, is afterwards acrimonious and burning; when swallowed, it produces vomiting and purging, and acts as an acrid poison; the persons who grind it suffer from headache and giddiness, and often from delirium. It principally consists of resin and a waxy matter, and a considerable quantity of malate of lime is also present. ROSÉ, in his researches, found euphorbium to contain two distinct resins: one, easily soluble in cold, the other, only soluble in hot alcohol, and, under certain circumstances, susceptible of crystallization. JOHNSTON has also examined these resins, but there is some doubt as to the results of the analysis. ROSÉ assigns the formula $C_{40}H_{35}O_4$ to the crystallizable resin. Euphorbium has also been examined by BUCHNER and HERBERGER, who regard one of the resins as basic, the other acid.

GALBANUM.—Much uncertainty exists with regard to the plant whence this gum-resin is derived. The Dublin College of Physicians have described galbanum,

on the authority of LINDLEY, as the exudation of the *Opöidia Galbanifera*. DON found an umbelliferous fruit in the galbanum of commerce, which he believed to be that of the plant yielding the gum-resin; and, as it constituted a new genus, he called it *Galbanum Officinale*. But though it is not at all improbable, says Dr. PEREIRA, that these fruits are the produce of the galbanum plant, yet no proof of this has been hitherto adduced, and Dr. LINDLEY, therefore, very properly asks, *Did the fruit found upon the gum really belong to it?*

It has not yet been precisely ascertained where galbanum is produced. DIOSCORIDES says it is obtained in Syria; a statement which is, perhaps, correct, though hitherto no evidence of this has been acquired. It is not improbable that it is also procured in Persia, or even in Arabia, as suggested by Dr. ROYLE. *Opöidia Galbanifera* grows in the province of Khorasan, near Durrood. The German pharmacologists distinguish two varieties—*Galbanum Levanticum* and *Galbanum Persicum*. The names indicate the localities whence they are supposed to be derived.—*Pereira*.

DESCRIPTION.—Galbanum generally occurs in brownish, or dark brownish-yellow, irregular masses of large size, apparently composed of agglutinated tears. Some of these, when broken, appear translucent, and of a bluish, or pearl-white color. Fragments of the stem and other similar impurities often pervade the tears; and, to remove these, the galbanum is generally subjected to fusion and strained.

Another variety of galbanum is known, but it is comparatively rare. It is in distinct, globular, yellowish tears of about the size of a pea, possessing a feebly resinous and yellow fracture.

PROPERTIES AND COMPOSITION.—Galbanum has a hot, acrid, and bitter taste, and a peculiar, balsamic odor. When subjected to cold, it is rendered brittle, and may be easily pulverized.

It has been analyzed by several chemists. PELLETIER's results are as under:—

	Centesimally.
Resin,	66.86
Gum,	19.28
Volatile oil and loss,	6.34
Ligneous matters and impurities,	7.52
Bimalate of lime,	traces.
	100.00

MEISSNER's results, appended, seem much more accurate:—

	Centesimally.
Resin,	65.8
Gum,	22.6
Bassorin,	1.8
Volatile oil,	3.4
Bitter matter, with malic acid,	0.2
Vegetal remains,	2.8
Water,	2.0
Loss,	1.4
	100.0

The volatile oil of galbanum is obtained by submitting the gum-resin, with water, to distillation. It is colorless and limpid. Its odor is like that of galbanum and camphor; its taste is hot, afterwards cooling and bitterish. It is soluble in alcohol, ether, and fixed oils.

The resin of galbanum is dark yellowish-brown, transparent, brittle, and tasteless; soluble in alcohol and ether; scarcely so in spirit containing fifty per cent. of water, or in almond oil; very slightly soluble in oil of turpentine, even when aided by heat. It dissolves in sulphuric acid, forming a dark yellowish-brown liquid.

PELLETIER states that galbanum resin has the remarkable property of yielding an indigo-blue oil when heated to from 248° to 266°. JOHNSTON assigns the formula $C_{40}H_{27}O_7$, as representing the composition of the resin.

USES.—Galbanum is principally employed in medicine; it is administered internally in catarrhs, sometimes in amenorrhœa and chronic rheumatism. Externally, it is applied as a mild stimulant, resolvent, or suppurant, in indolent swellings.

GAMBOGE—*Gomme gutte*, French; *Gutti*, German; *Cambogia*, Latin—is, according to GRAHAM, the produce of *Hebradendron Cambogioides*, a native of Ceylon. Gamboge appears to have been first noticed in 1605 by CLUSIUS, who received some of it in 1603 from PETER GARET of Amsterdam. Admiral VAN NECK had brought this from China, and, according to him, its oriental name was *Ghittaiemou*. In Siam it is obtained, says KONIG, by fracturing the branchlets and leaves, when a yellow milky juice exudes, which is collected either upon the leaves of the tree, or in cocoa-nut shells, from which it is transferred to flat earthen vessels, and allowed to inspissate in the atmosphere; it is finally enveloped with leaves. The cylindrical kind of gamboge is resolved into this form by being deposited, while semi-fluid, in joints of the bamboo.

MURRAY states that gamboge is obtained in Ceylon by wounding the bark of the tree, at the time of flowering, with a sharp stone.

DESCRIPTION.—For the delineation of the different varieties of gamboge, the Editor has to resort to the *Materia Medica* of Dr. PEREIRA as the best source of information on the subject. That eminent authority says:—Two kinds of gamboge are described by pharmacological writers—the Siam and the Ceylon. Of these the first only is known in commerce.

1. *Siam Gamboge*.—This is the gamboge of the shops. It is brought to this country sometimes direct from Siam; at other times indirectly by way of Singapore, Penang, or Canton. It presents itself in commerce in three forms:—1, in rolls, or *solid* cylinders; 2, in pipes, or *hollow* cylinders; 3, in cakes or amorphous masses. The first two varieties are known commercially as *pipe* gamboge. The commonest pieces of the above are called *coarse* gamboge.

a. Pipe gamboge consists of cylindrical pieces, varying in size from one to three inches in diameter. Some of them appear to have been formed by rolling; but many of them are striated, from the impression of the bamboo into which the gamboge juice has been run, and, not unfrequently, portions of the stem are still adherent. The gamboge cylinders are sometimes distinct, and covered externally with a dirty greenish-yellow dust; at other times agglutinated, or even folded so as to form masses of varying sizes and shapes.

Pipe gamboge occurs in all qualities, the finest and the worst specimens having this form. *Fine gamboge* is brittle and devoid of odor. It has very little taste at first; but, after some time, it causes an acrid sensation in the throat. Its fracture is conchoidal, and the resulting surfaces are opaque reddish-yellow, with a glimmering lustre. It is completely dissolved by the successive action of ether and water. With a sufficient quantity of the latter fluid, it forms a yellow emulsion, the films of which are good microscopic objects for the observation of *active molecules*. The powder of fine gamboge is bright yellow.

Inferior qualities of this gum-resin are harder, more earthy in fracture. The fresh surfaces are brownish or greyish-yellow, frequently with black spots from the intermixture of foreign bodies. Ether and water successively employed do not completely dissolve it. Iodine readily detects starch in the cooled decoction by the green color which it gives rise to.

b. Lump or cake gamboge occurs in masses of several pounds' weight. Its quality is inferior to the finest pipe kind. Internally, fragments of wood, twigs, and air-cells may be observed. In most of its characters it agrees with the inferior qualities of pipe gamboge, and, like these, contains starch.

2. *Ceylon or Cingalese Gamboge*.—Dr. PEREIRA was unacquainted with this kind of gamboge, which is unknown in English commerce. According to Dr. CHRISTISON, it is usually in small, irregular fragments; but, as originally collected, is in flattish round masses—as if moulded in shallow bowls—weighing about a pound or upwards, and it appears to be composed of aggregated irregular tears, with interspaces and cavities, which are lined with a dark pulverulent matter, or with a powder of an earthy appearance. Altogether it seems a very coarse article. It forms, with great ease, an emulsion nowise inferior in smoothness, and very little, if at all, in brightness of tint, to that of the very best pipe gamboge of Siam.

PROPERTIES AND COMPOSITION.—The properties of gamboge have been, to some extent, treated of in the foregoing description. The following are additional reactions:—

Gamboge affords orange-red tinctures with ether and alcohol, which, when dropped on water, yield, on the evaporation of the solvent, thin, bright yellow, opaque films, which readily dissolve in caustic potassa. The resinous portion of gamboge, of which these films are constituted, has been termed by JOHNSTON gambogic acid. The potassa salt, obtained as just noted by the solvent power of the alkali, gives with acids a yellow precipitate of gambogic acid; with acetate of lead, yellow; with sulphate of copper, brown; and with the salts of iron, dark brown deposits.

* Should it be necessary, as it sometimes has been in medico-legal cases, to detect the presence of gamboge amongst other vegetal products, as in pills, *et cetera*, the following simple, but sure, course of procedure may be adopted:—

Digest one portion of the suspected substance in alcohol, and another in ether, and subject the tinctures to the above-mentioned tests. Though the yellow resin of New Holland, the produce of the *Xanthorrhœa*

Hastilis, has a similar appearance, yet its chemical reactions with the tests above-mentioned are very different. Should the yellow coloring matter of turmeric, saffron, or rhubarb be taken, at first sight, for that of gamboge, the examination with acids, acetate of lead, sulphate of copper, and salts of iron successively, may be accepted as positive.

Dr. CHRISTISON gives the following as the centesimal composition of gamboge:—

Siam Gamboge.			
	Pipe.	Cake or Lump.	Coars.
Resin,.....	72.5	64.7	48.2
Soluble gum,.....	22.7	20.3	15.2
Woody fibre,.....	trace	5.3	13.3
Pecula,.....	—	5.6	14.5
Moisture,.....	4.8	4.1	8.8
	100.0	100.0	100.0

Ceylon Gamboge.	
Resin,.....	71.2
Soluble gum,.....	19.9
Woody fibre,.....	5.7
Water,.....	3.2
	100.0

GAMBOGIC ACID.—Syn. Gambodic acid—Resin.—It has a deep orange color, and communicates a yellow tint to ten thousand times its weight of alcohol. It is soluble in this menstruum, and still more so in ether. Water does not take up any of it. When subjected to a heat of about 400° it is partially decomposed, so that while one portion is soluble in alcohol, as the original resin, the other is insoluble. Gamboge resin forms numerous salts. Its composition has been represented by the above chemist as $C_{40}H_{22}O_9$. The gum of gamboge seems to be identical with arabin, and like it readily dissolves in water.

The fecula found in the inferior kinds of gamboge is probably an adulterant.

To a small extent gamboge is employed as a water-color; but its principal application is in medicine. It is seldom administered *per se*, owing to its tendency to create nausea and vomiting; but, when combined with milder purgatives, it has been found to be a valuable remedy in constipation; in cerebral affections, as apoplexy; in dropsy; and as an anthelmintic. The full dose of it is said to be from ten to fifteen grains. In excessive quantity it acts as an acrid poison. Dr. PEREIRA records that a drachm administered to a human subject, caused horrible vomiting and purging, followed by syncope and death. No effective antidote is known. HAHNEMANN has, indeed, recommended carbonate of potassa as a means of diminishing the violence of the topical action of gamboge.

MYRRH.—*Myrrhe*, French; *Myrrha*, German; *Myrrha*, Latin. This well-known gum-resin is the spontaneous exudation of the *Balsamodendron Myrrha*. It is repeatedly mentioned in the Old Testament, the earliest allusion being in Genesis, from which it appears that 1729 B.C. it was an article of Eastern commerce. It seems to have been made use of by DEMOCRATES. DIOSCORIDES enumerates several varieties of it; one named the *Troglodytica* being the best. According to some ancient writers, this gum-resin received its

appellation from MYRRHA, the daughter of CIMFRAS, king of Cyprus, who, after committing criminal acts, absconded to Arabia, and was transformed into a tree, which ever afterwards bore her name.

The myrrh tree was not fully known until EHRENBURG, in 1825, returned from his travels with HEMPRICH in Asia and Africa, bringing with him a specimen, which has been delineated and depicted by NEES VON ESENBECK.

DESCRIPTION.—Myrrh, says Dr. PEREIRA, is imported from the East Indies in chests containing from one to two hundredweight each. Formerly the finest kind was brought from Turkey, and an inferior one from the East Indies; but, at the present time, nearly the whole comes from India. Sometimes the same chest contains myrrh of all qualities, which is then termed *myrrh in sorts*; but commonly it is imported more or less assorted.

Myrrh of first quality.—Turkey myrrh occurs in pieces of irregular forms and of variable sizes, consisting of tears—either distinct or agglomerated—usually covered with a fine powder or dust. The color varies, being pale reddish-yellow, red, or reddish-brown. The pieces are fragile, semi-transparent, with a dull, and in part splintery, fatty kind of fracture. In consequence of imperfect desiccation, the largest and finest pieces often present internally, opaque, whitish, or yellow striæ, or veins, which have been compared by DIOSCORIDES, PLINY, and many others, to the white marks on the nails. The purest, palest, and most odorous pieces are sold as *picked myrrh*.

Myrrh of second quality consists of distinct tears or grains, which are rounded or irregular, and vary in size from that of a pin's head to a peppercorn, none of them in Dr. PEREIRA's specimens being so large as a small pea. They are somewhat shiny, more or less transparent, and vary in color from pale or whitish-yellow to reddish-brown. It consists of tears of myrrh, intermixed with fragments of gum-arabic, and of some resin very like mastic or juniper. Many druggists regard it as merely the siftings of the finest kind, but Dr. PEREIRA does not agree with this opinion.

Myrrh of third quality.—Formerly this was the only kind imported from the East Indies. It occurs in pieces, which are darker-colored than those of the so-called Turkey myrrh, and the average size of which does not exceed that of a walnut. It is often mixed with other matters, particularly with *Indian bdellium*, and with a substance of similar appearance to dark-red colored Senegal gum.—*Pereira*.

PROPERTIES AND COMPOSITION.—The odor of myrrh is peculiar, but balsamic and fragrant; the taste is bitter, aromatic, and somewhat pungent. Water dissolves the gum principally, while alcohol and ether take up the volatile oil and resin. Myrrh is readily dissolved by the alkalis. When it is subjected to the action of nitric acid, a vinous hue is produced. According to PELLETIER it consists of thirty-four per cent. of resin and sixty-six of gum. RUICKHOLDT states that it contains, when of the best quality, between forty-four and forty-five per cent. of resin. BRANDES and BRACONNOT have also analysed it, with the following results:—

	Centesimally represented	
	Brandes.	Braconnot.
Volatile oil,.....	2.60	2.5
Resin,.....	27.80	23.0
Gum { Soluble,.....	54.38	46.0
Insoluble,.....	9.32	12.0
Salts—benzoates, malates, phosphates, sulphates, and acetates of potassa and lime,.....	1.36	—
Impurities,.....	1.60	16.5
Loss,.....	2.94	
	100.00	100.0

According to BRANDES, the 27.80 per cent. of resin found by his analysis, consisted of 22.24 soft, and 5.56 of hard resin, the two soluble in alcohol. The former he distinguishes as odorous, and insoluble in ether. UNVERDORBEN regards it as a compound of hard resin and volatile oil. The hard resin is characterised as inodorous, soluble in the caustic alkalies, but not taken up by ether. The resin prepared by RUCKHOLDT was of a brown color, fused at a temperature below 212°, and slightly retained the taste and odor of the gum-resin. By subjecting it to heat, he obtained a modified resin, which he has termed myrrhic acid.

The volatile oil of myrrh has the odor and taste of myrrh; it is soluble in alcohol, ether, and the fixed oils; it is thin, but has a specific gravity higher than that of water. It is devoid of color, but becomes yellowish by keeping, probably from the absorption of oxygen. It forms red menstrua, with sulphuric, nitric, and hydrochloric acids. When exposed to the atmosphere, partial evaporation occurs, and a glutinous, varnish-like magma remains.

The Editor learns that myrrh is often mixed with Indian bdellium—the produce of the *Amyris commiphora*. *Bdellium*, in appearance and taste, is often very similar to myrrh, but differs in odor, and is characterized by its great amount of bassorin. Besides this, it is often mixed with another substance, for the detection of which BLEY and DIESEL give directions as follows:—

Pseudo-myrrh, which has been frequently found incorporated with the genuine myrrh, consists of large pieces of different forms, the majority of them seeming to be fragments of a cylindrical body; they are coated externally with dust, and have a dirty reddish-brown color; the surface of fracture is tolerably even, of vitreous lustre, brownish-yellow color, and nearly as transparent as Senegal gum. It has a faint myrrh-like odor, and a disagreeable, bitter, somewhat balsamic taste. Nitric acid dissolves it, yielding a bright yellowish liquid, from which water separates small yellowish particles. Genuine myrrh yields with nitric acid a transparent dirty-yellow liquid. *Bdellium indicum* is not dissolved by nitric acid; it softens, becomes whitish and opaque. Bibulous paper, moistened with the alcoholic extract of myrrh, and then with nitric acid, acquires the blood-red color first observed by BONASTRE; *bdellium* and pseudo-myrrh exhibit only a yellow or brownish coloring. *Bdellium indicum* is, moreover, distinguished by its greenish-brown hue, its more terebinthinate odor, and bitter and somewhat acrid taste. It becomes viscous when held for some time between the fingers. Myrrh yields a bright

golden-yellow tincture, and an opaque whitish residue; pseudo-myrrh, a high yellow one, and a semi-transparent residue; *myrrha indica*, a dark-yellow tincture, and an opaque residue. An addition of water produces in the first and last a milky turbidness, and in the second no change. Nitric acid—six drops to twenty of the tincture—yields with *myrrha electa* a yellowish-white opacity, upon which, after a time, the periphery of the liquid acquires a bright violet color, while the centre remains yellow. *Myrrha indica* behaves similarly, only that the tint is darker; pseudo-myrrh does not exhibit this reaction. Fuming nitric acid produces with the tincture of *myrrha electa* an amber-brown, and finally a dark violet color; on evaporation, a dark gamboge-looking residue is left; *myrrha indica* exhibits the same reaction; pseudo-myrrh experiences no change. *Bdellium indicum* and *africanum* are distinguished by their not assuming a violet hue on their treatment with nitric acid. About two grains of myrrh, shaken with an ounce of water and filtered, yield with solutions of salts of the oxide of lead a considerable precipitate. *Bdellium indicum*, treated in the same manner, exhibits scarcely any opacity.

USES.—Like most of the other gum-resins, myrrh is employed only in medicine; it is useful in disordered conditions of the digestive organs; in excessive secretions from the mucous membrane; and, externally, as a dentifrice, and as a gargle for ulceration of the throat in the form of tincture.

OLIBANUM.—*Oliban*, French; *Oelbaumharz*, German; *Olibanum*, Latin. This gum-resin, employed by the ancients in their religious rites under the name of *frankincense*, and first mentioned by MOSES, is derived from the *Boswellia Thurifera*, a terebinthaceous tree, inhabiting the mountainous parts of Coromandel.

DESCRIPTION.—Dr. PEREIRA describes it as consisting of round, oblong or ovate, pale-yellowish, semi-opaque, fragile tears, having a balsamic resinous odor. JOHNSTON is of opinion that it is a mixture of two distinct gum-resins. The one he delineates as consisting of opaque, dull, hard, brittle pieces, which, when introduced into alcohol, become almost immediately white and opaque, from a white powdery coating or crust left on their surface as the soluble portion is taken up. This variety constitutes the larger portion of the olibanum of commerce, and is the more fragrant when burned. It contains an acid resin and volatile oil.

The second variety is characterised as being in clearer, more yellow, less brittle, opaque pieces, generally in long tears as they have flowed from the tree, containing less gum than the other kind, and becoming clear and transparent when immersed in alcohol. All the tears of olibanum experimented upon by Dr. PEREIRA became opaque when introduced into alcohol.

COMPOSITION.—Olibanum has been examined by BRACONNOT, who gives the following as its centesimal composition:—

	Per cent.
Resin,.....	56.0
Gum,.....	30.0
Volatile oil,.....	8.0
Matter like gum, insoluble in water and alcohol,.....	5.2
Loss,.....	0.8
	100.0

Dr. STENHOUSE, who examined the volatile oil of olibanum, found it to be colorless, and similar to turpentine, but possessed of a more agreeable odor. Its composition is represented by the formula $C_{35}H_{28}O$.

JOHNSTON has distinguished two distinct resins, produced by both varieties of the gum-resin before-mentioned. The resin from the first of these gave the composition $C_{40}H_{32}O_6$. That from the second, consisting of the clearer, yellower, elongated tears, resembles colophony, and its formula is $C_{40}H_{32}O_4$.

USES.—Olibanum is, to a great extent, disused for medical purposes. It was formerly administered in chronic diarrhoea, old catarrhs, and in affections of the chest. It is sometimes employed for fumigation, and enters into the incense employed in the services of the Roman church.

OPOPONAX.—*Opopanax*, French, German, and Latin.—This gum-resin is the inspissated juice of the *Opopanax Chironium*, a plant flourishing in Greece, Italy, Sicily, and in the South of France, and bearing a great similarity to parsnip. It was employed by HIPPOCRATES, and is mentioned both by DIOSCORIDES and by THEOPHRASTUS.

Opopanax occurs in reddish tears and lumps, tasting acrid and bitter, and possessing a mouldy, disagreeable odor. The following is its constituents, as ascertained by PELLETIER:—

	Centesimally.
Resin,	42·0
Gum,	33·4
Lignin,	9·8
Starch,	4·2
Wax,	0·3
Extractive,	1·6
Malic acid,	2·8
Volatile oil, traces of caoutchouc, and loss,	5·9
	100·0

On evaporating the spiritous solution of opopanax, a transparent brown resin, having a peculiar odor, is obtained. It readily fuses at 212° , and, after remaining for a short time at that temperature, becomes brittle upon cooling. It dissolves in alcohol and ether, and in the caustic alkalies. The alkaline solution is reddish, and parts with the resin, on the addition of hydrochloric acid, in yellow flocculi. Its composition, as it exists in the natural gum-resin, is as under:—

	At weight.	Centesimally.	
		Theory.	Johnston.
40 Eqs. Carbon,	240	63·67	64·01
25 Eqs. Hydrogen,	25	6·63	6·75
14 Eqs. Oxygen,	112	29·70	29·24
1 Eq. Opopanax resin, ..	377	100·00	100·00

USES.—Opopanax was formerly employed in medicine, but it is now banished from the *Materia Medica* as enumerated in the British Pharmacopeias. It is adapted to the same cases as the other gum-resins of this class. Dr. PEREIRA is of opinion, that it is more allied to ammoniacum than to any other of these substances.

SAGAPENUM.—*Sagapenum*, French and German; *Sagapenum*, Latin.—Sagapenum is mentioned, says Dr. PEREIRA, by HIPPOCRATES, DIOSCORIDES, and PLINY. The latter calls it *sacopenium*. DIOSCO-

RIDES says it is a liquor obtained from a ferulaceous plant growing in Media. Nothing is known with respect to the plant yielding sagapenum. WILLDENOW considered it to be *Ferula Persica*, and he has been followed by SPRENGEL and others; but there is no evidence to prove that sagapenum is obtained from a *Ferula*, for the statement of DIOSCORIDES cannot be admitted as having much weight.

BRANDES' analysis of sagapenum gave the following results:—

	Centesimally.
Resin,	50·0
Gum, with calcareous salts,	32·5
Volatile oil,	3·5
Bassorin,	4·2
Malate and phosphate of lime,	1·1
Impurities,	4·2
Water,	4·5
	100·0

Sagapenum of the finest kind consists of masses made up of agglutinated, brownish-yellow, semi-transparent tears, resembling galbanum, but having a darker color and a more alliaceous odor. A more common sort occurs in soft, tough masses, in which no distinct tears are to be seen. Its taste is hot and acrid, and, when heated, it evolves a much more aromatic and agreeable odor than galbanum. It is imported from the Levant.

The oil of sagapenum has a mild bitter, alliaceous taste, subsequently becoming hot; its odor is also garlicky. It is of a pale yellow color, dissolves in alcohol and ether, and is reddened by sulphuric acid. Its specific gravity is greater than that of water.

The resin of sagapenum has been examined by JOHNSTON, who gives, as the representative of its composition, the formula $C_{40}H_{32}O_6$. It possesses a strong garlic odor, and easily fuses, becoming fluid at 212° . Ether resolves it into two resins:—

1. The resin *insoluble in ether* is devoid of taste and odor, and is of a brownish-yellow tint. It is soluble in alcohol and the alkalies, but is not taken up by oils of turpentine and almonds.

2. The resin *soluble in ether* possesses the odor of sagapenum in a slight degree; its taste is mild, subsequently bitter; its color, reddish-yellow. It is soluble in alcohol, and partially so in oils of turpentine and almonds. Sulphuric acid dissolves it, forming a blood-red menstruum, from which a violet-tinged matter is separated by the addition of water.

USES.—The medicinal effects and uses of sagapenum are similar to those of asafetida,—see page 322. It is now very little employed.

The Editor thinks it most remarkable that so little is really known with respect to the previously-cited compounds. There is now a great field open to young chemists to investigate their nature and true composition, *et cetera*, so as to remove many of the inaccuracies regarding them.

STATISTICS.—The Returns of the Board of Trade for 1850 to 1855 only enumerate Ammoniacum, Asafetida, Euphorbium, Gamboge, Myrrh, and Olibanum. Annexed are the imports and exports of these for the years 1850, 1851, 1852, 1853, 1854, and 1855:—

GUN-COTTON.—*Coton-poudre*, French.—Some years ago this substance created quite a *furor* in the scientific world; but the expense of gun-cotton is considerably higher than that of gunpowder, and this with other drawbacks has been a great obstacle to its being extensively used. Ordinary cotton is one of the almost innumerable forms of lignin, a compound of carbon, oxygen, and hydrogen; but, by subjecting cotton to the action of nitric acid, a new element enters into the composition—namely, nitrogen, which is found in nearly all explosive bodies.

The action of nitric acid on vegetal matter had long attracted the attention of chemists before the discovery of the remarkable detonating compound now under notice. In 1813, BRACONNET gave an account of a new substance obtained by the action of concentrated nitric acid on starch, sawdust, linen, and cotton wool. He named this xyloidin, from the Greek word signifying wood, and described it as being white, pulverulent, neutral, and very inflammable. It is easily formed by boiling starch for a few moments in concentrated nitric acid, until solution takes place; on pouring the resultant into cold water, the xyloidin is precipitated, and may be collected and exsiccated. In 1838, PELOUZE called the attention of the Academy of Sciences to the properties of xyloidin, which he observes is very combustible, taking fire at 365°, burning with great rapidity, and almost without residue. This property led him to an experiment which he thought susceptible of some applications, especially in artillery. By plunging paper in nitric acid, specific gravity 1·5, leaving it there the requisite time for the acid to permeate the paper, which is usually accomplished in two or three minutes, then withdrawing it, and, lastly, washing it in water, a kind of parchment impermeable to moisture, and extremely combustible, is obtained. DUMAS proposed to name the compound *nitramidine*, and mentions the application of paper and pasteboard prepared by nitric acid for fireworks.

At a meeting of the British Association at Southampton, in 1846, it was stated that Professor SCHÖNBEIN had discovered a mode of rendering cotton so detonating as to form an excellent substitute for gunpowder. Soon after this announcement, Professor OTTO of Brunswick published an account of an explosive cotton, as did also MOREL of Paris, and BÖTTGER of Frankfort. SCHÖNBEIN undoubtedly, as

DUMAS admits, deserves the honor of having been the first to show that the products of the action of nitric acid upon lignin are superior in explosive energy to gunpowder; but it must be recorded that, as far back as 1832, ROBIQUET produced an insoluble powder, explosive when heated, by the addition of water to a solution of sawdust in strong nitric acid. In April, 1847, SCHÖNBEIN's patent was enrolled; the specification states, that in preparing the cotton the patentee uses nitric acid of specific gravity 1·45 to 1·50, and sulphuric acid of specific gravity 1·85. These acids are to be mixed in the proportion of three parts of the latter to one of the former; the mixture is allowed to cool down to between 50° and 60°, and then rough cotton, free from all extraneous matter, is immersed in the liquid, in as open a state as possible, in a porcelain vessel. When thoroughly soaked, the excess of acid is to be drawn or poured off, and the cotton squeezed lightly with an earthen presser to separate the principal part of the acid. The cotton is covered over and left for an hour, then pressed, and well washed in running water, to get rid of all free acid; it is next to be partially exsiccated by pressure, and to insure its freedom from acid, it is to be washed in a dilute solution of carbonate of potassa, made by dissolving one ounce of this salt in a gallon of water; it is then put in a press, and the excess of alkaline solution squeezed out, leaving the cotton nearly dry. It is next washed in a solution consisting of one ounce of pure nitrate of potassa in one gallon of water, and when again pressed is dried in a room heated by steam or hot water to the temperature of from 150° to 170°. The saltpetre appears to increase the explosive force of the cotton, but it is not absolutely necessary. Of the cotton thus prepared, three parts are said to be equal in force to eight parts of Tower-proof gunpowder.

A simpler method of preparing gun-cotton in small quantities was proposed by Mr. THOMAS TAYLOR in 1846, which is to mix in any convenient glass vessel an ounce and a half, by measure, of nitric acid—specific gravity 1·45 to 1·50—with an equal quantity of sulphuric acid—specific gravity 1·80. When the mixture has cooled, place one hundred grains of fine cotton wool in a mortar, pour the acid over it, and with a glass rod imbue the cotton as quickly as possible with the acid. As soon as the cotton is completely satu-

rated, remove the acid, and, with the aid of a pestle, quickly squeeze out as much liquid as possible. Throw the mass into a basinful of water, and thoroughly wash it, either in successive portions of water or under a tap, until the cotton has not the slightest acid taste. Finally, squeeze it in a linen cloth, and dry it in a water-bath. Nitric acid of the specific gravity of 1.50 answers better than that of 1.45, the cotton being much less acted upon by the strong acid. Nitric acid of the specific gravity 1.36 converts the cotton into a gelatinous mass.

Gun-cotton is considerably heavier than unprepared cotton, and may be distinguished therefrom by its harshness, and by the crepitating sound produced when pressed by the hand. When well made, there is scarcely any change in color or general appearance. It may also be known from common cotton by its electric condition; for if a portion be pulled briskly between the finger and thumb of a dry hand, the fibres will adhere with great tenacity. If a strip of prepared paper be thus treated, it will, on presenting one end to the knuckle, be alternately attracted and repelled, and thus part with its electricity. Gun-cotton is also perfectly soluble in ether, and if the solution be poured on the surface of cold water, the xyloidin yields an opaque film thereon, which, when collected and dried, forms a remarkably explosive paper.

The detonating character of gun-cotton appears to be due to the formation of xyloidin in the tubes and upon the exterior of the cotton fibre, under the action of the nitric acid. Gun-cotton explodes with very great rapidity at from 350° to 400°. If a little gunpowder be placed on a sheet of writing paper, and a small piece of gun-cotton be laid lightly upon it, and the whole held about a foot above the flame of a lamp or candle, the heat will soon be sufficient to ignite the cotton, but the powder will not be kindled; and, although the cotton explodes in contact with the powder, its action is so rapid that there is not time enough to raise the gunpowder to the temperature required for its explosion. This great rapidity of action is opposed to its utility for propulsive purposes. It is well known to practical men that a tardily-exploding material is the best for artillery practice. Thus, when a slow powder is used, the ball acquires a slight degree of motion, which is imparted to the air in front of it, before the full power of the detonation is exerted; and that motion is gradually increased during the remainder of the explosion. But if the action takes place too quickly, the full force of the propelling power comes into play before the ball is in motion, and the bursting of the gun is the probable consequence. This is the reason why the fulminates of mercury and silver have not been more extensively used in warfare.

When gun-cotton has been carefully prepared, the products of its combustion are carbonic acid, aqueous vapor, and free nitrogen. In some cases nitrous acid is produced, owing to defective washing; and when nitrate of potassa has been employed, or, in fact, a solution of any salts, a dense white vapor accompanies the explosion. The quantity of water produced during the decomposition of the cotton by heat is so great, as to constitute an objection to its use

in fire-arms. Its hygrometric condition also impedes its utility; for if a quantity be exposed for an hour or two to a damp atmosphere, it absorbs nearly its own weight of water, and requires re-drying before it can be employed; it cannot be protected from atmospheric moisture by compression into cartridges, as in that state it does not explode with certainty. The idea of using the fulminating cotton as a substitute for gunpowder for artillery purposes, seems to be completely abandoned; but on account of the small quantity of smoke given off, as well as on account of its enormous force, it is much used for mining purposes, the proportionate quantity employed being a fourth of that of powder.—*Tomlinson*.

In the explosion of gun-cotton there appear to be found very decided quantities of nitrous and of hydrocyanic acid. The former corrodes fire-arms, and the latter vitiates the surrounding air in a mine.

The most recent and best information on gun-cotton and its substitution-compounds is given in a paper by Mr. EDWARD HADOW, from which the following interesting details are transcribed.

Analyses of gun-cotton have been published by PELOUZE, PELIGOT, GLADSTONE, PORRETT, RANSOME, and likewise by SCHÖNBEIN; they exhibit, however, a remarkable want of agreement with each other, both in the formulæ to which they give rise, and in the per-centage increase of weight which they would represent the cotton to have obtained on its transformation into gun-cotton.

PELOUZE states that cotton constantly gains from seventy-four to seventy-six per cent., giving the formula $C_{24} H_{17} O_{17}, 5 NO_5$, corresponding to an increase of seventy-five per cent. exactly. PELIGOT's formula is $C_{12} H_9 O_9, 3 NO_5$, according to which the gain must be 94.4 per cent. RANSOME obtained $C_{12} H_8 O_{10}, 2 NO_5$, which represents an increase of 65.4. Dr. GREGORY states it to be 69.5, which corresponds with that required by the formula which GLADSTONE ascribes to the most explosive gun-cotton, $C_{24} \left\{ \begin{matrix} H_{15} \\ 5 NO_4 \end{matrix} \right\} O_{20}$,

while the formula of PORRETT and TESCHEMACHER, $C_{12} H_8 O_8, 4 NO_5$, would double the original weight of the cotton. SCHÖNBEIN merely gives the per-centage of carbon, nitrogen, hydrogen, and oxygen, from which the lowest formula that can be calculated corresponds nearly to $C_{47} H_{31} O_{68} N_{10}$. In consequence of this disagreement between the formulæ, giving rise to so marked a difference in the per-centage increase of weight deduced from them, it was evident that a careful determination of the weight actually acquired by cotton, after immersion in acids, could alone throw much light on the matter, by pointing out the formula upon which most reliance was to be placed, and from which the composition of the soluble variety might be determined, provided that it were indicated by a definite and constant increase of weight. While ascertaining this point, HADOW was anxious likewise to discover what strength and what proportions of acids were capable of producing the soluble gun-cotton, as well as whether there were more than one such compound; expecting that, if such were the case, there would be always an augmentation of weight closely correspond-

ing to two or more numbers from which formulæ might be calculated, or by which at least the results of analyses might be controlled.

In the preparation of these compounds, nitric acid was not used alone, since a very slight difference in strength produced a great difference in the result. HO, NO_5 gives an insoluble product, while $\text{HO}, \text{NO}_5 + \text{HO}$ destroys the texture of the cotton; and having ascertained that when sulphuric acid is used, no trace of it exists in any of the compounds, a mixture of the two was always used; the latter acid being advantageous for the purpose of increasing the bulk of the mixture, retaining the water abstracted from the cotton, and preventing the solution of the compound, which takes place to a greater or less extent in nitric acid *per se*. The mixtures were likewise made in atomic proportions, that their formulæ might be easily retained in the memory, and similar mixtures be prepared from acids of various strengths. After some trials, those which contained one equivalent of monohydrated nitric acid with two equivalents of monohydrated sulphuric acid, proved to be best; and mixtures being made with the acids in this proportion, and from one to five additional equivalents of water, the fifth was found to disintegrate the cotton. The results obtained from one hundred of cotton were as follow:—

$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\}$	$2 \text{ HO} = 177$	} Insoluble in ether + one-eighth alcohol except the last, which is slightly attacked.
$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\}$	$2 \text{ HO} = 176$	
$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\}$	$3 \text{ HO} = 171.7$	
$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\}$	$4 \text{ HO} = 157$	} Very soluble.
$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\}$	$5 \text{ HO} = \frac{\text{about}}{140}$	
		} Soluble in great measure.

The interval between the third and fourth appeared in some degree to correspond to what had been expected. That between the fourth and fifth was doubtful, from the loss of the latter, and from its apparently containing an admixture of unchanged cotton; but on trying fractional additions of water, a corresponding intermediate increase of weight was likewise produced in the cotton: for example,

$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\} 3\frac{1}{2} \text{ HO} = 166.4$ $\left\{ \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\} 3\frac{2}{3} \text{ HO} = 160.5$
both compounds proving perfectly soluble. It was likewise found on repeating these experiments, that it was difficult to obtain the same increase of weight unless the mixture corresponded accurately in composition. The cotton in these researches was thor-

oughly exsiccated in a current of dry air at 212° , and in consequence of its hygroscopic properties, was weighed in the same tube in which the desiccation took place. At first the gun-cottons were likewise carefully dried at low temperatures, after thorough washing in distilled water; but the results not being found quite accurate, and a gradual loss of weight being observed at temperatures below 212° , the drying was effected by placing them *in vacuo* over sulphuric acid for twenty-four hours, after which they were found not to sustain the slightest diminution in weight. The acids were also used in large proportion to the quantity of cotton, that the water abstracted might have no appreciable effect in diluting the mixture; and as a precaution, the immersion was continued for several hours, although the full effect appears to be produced in a very short space of time. It was, however, found that, notwithstanding these advantageous conditions for the production of definite compounds, very variable increments of weight were acquired by the cotton, ranging from about forty per cent. upwards.

Immersion in acids previously warmed was then tried, but as the cotton was found to lose weight in proportion to its duration, owing to a slow solution even at 120° , nothing could be learnt from the weighing of the compound; in other respects, however, the result of the experiment with hot acids proved curious and interesting, from the fact that

$\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\} 3 \text{ HO}$, which at 60° gave rise to an almost insoluble compound, produced at 130° one perfectly soluble in ether + $\frac{1}{5}$ alcohol: the other acid mixtures, containing more than three equivalents of water, produced soluble compounds, both at 60° and 130° , but their solutions differed remarkably in one respect; for all soluble products formed at ordinary temperatures, when dissolved in the proportion of six grains to the ounce, yield thick glutinous solutions, while all those which are the result of acids at the temperature of 130° , give perfectly fluid ones, which produce, on drying, membranes far exceeding the former in strength and toughness, and much better adapted to photographic or surgical purposes. By far the best mixture for producing collodion-wool is that represented by the formula $\left. \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\} + 3.5 \text{ HO}$, which is obtained by mixing eighty parts by weight of nitric acid, specific gravity = 1.424, with one hundred parts by weight of sulphuric acid, specific gravity = 1.833; as—

Sulphuric acid, specific gravity, 1.833,	=	$2 (\text{HO}, \text{SO}_3 + 0.33 \text{ HO})$	=	103.9
Nitric acid, specific gravity, 1.424,	=	$(\text{HO}, \text{NO}_5 + 2.84 \text{ HO})$	=	88.5
$\text{HO}, \text{NO}_5 + 2 (\text{HO}, \text{SO}_3) + 3.5 \text{ HO} = 192.4$				

These specific gravities are especially referred to, from their being those of the acids most frequently met with in commerce. Good collodion-wool is also produced by stronger acids, if there be *not less* water than that required by the formula $\left\{ \begin{array}{l} \text{HO}, \text{NO}_5 \\ 2 (\text{HO}, \text{SO}_3) \end{array} \right\} + 3 \text{ HO}$, and the temperature is raised to 130° ; however, the stronger the acids, the more liable is the collodion-wool to be-

come partially insoluble after drying. If there be less than three additional equivalents of water, the products are equally insoluble whether the acids are employed hot or cold.

Finding that the weighing of the product resulting from the action of warm acids could be of no service in proving the existence of definite compounds, Mr. HARDWICK's suggestion was tried—the effect of reim-

mersing the cotton in a portion of the same cold acid mixture with which it had been previously treated, noting at the same time whether any second increase of weight was obtained. The results were highly satisfactory. For the preparation of the highest compound, a mixture was made of two volumes of the strongest sulphuric and one volume of colorless nitric acid, specific gravity = 1.521.

27.5 grains of cotton, after some hours' immersion, weighed after washing and drying *in vacuo*, 49.88 grains, corresponding to a gain of 81.34 per cent. In this case, it was hardly expected that a second immersion would cause an increase; by experiment it was found to have sustained a slight loss, as it now weighed 49.62, showing that acids have a slight solvent power, even at ordinary temperatures. This increase of 81.34 per cent. in weight does not correspond with any of the analyses hitherto published, although the greatest care was taken to avoid error, on account of the important aid it would afford in deducing a formula for this and other compounds.

Another mixture agreeing with $\left\{ \begin{array}{l} \text{HO, NO}_3 \\ 2 \text{ (HO, SO}_3 \end{array} \right\} + 4 \text{ HO}$, gave at the first immersion an increase of 58.7 per cent.; by a second it was found to have increased to 62.9 per cent., thus fully answering expectations. A third immersion brought it to sixty-four per cent.

On account of the great difference observed between the products of $\left\{ \begin{array}{l} \text{HO, NO}_3 \\ 2 \text{ (HO, SO}_3 \end{array} \right\} + 3 \text{ HO}$, and the same $+ 4 \text{ HO}$, an intermediate mixture was made. The first submersion gave an increase of 67.3 per cent.; a second, 70 per cent.; a third, 71.4 per cent. Hence it was concluded that there were at least three compounds, of which, from one hundred of cotton, there would be obtained quantities approximating to one hundred and sixty-four, one hundred and seventy-two, and one hundred and eighty-two; and it is probable that any acid mixture would produce such a definite compound, were it not diluted at the same time by the water it abstracts, which, when the dilution exceeds a certain point, gives rise to a second compound, the great mass of the liquid probably having but little influence, in consequence of the imperfect diffusion arising from the want of perfect fluidity, and the adhesion to the fibres of the cotton; the washing and *thorough* drying then enable the original acid mixture to raise the second compound to that which would have resulted in the first instance had no dilution occurred. It is evident, also, that the number of immersions required must vary, according as the acid mixture is much within or approaches near to that state of dilution which limits its power of producing a certain compound, a given quantity of water having much more effect in one case than in the other.

In trying the effect of various reagents on gun-cotton, HADOW ascertained that it could be perfectly restored to the original cotton, without loss of form, by means of hydrosulphide of potassium, KS, HS. At Dr. MILLER's suggestion, this was made use of, to effect the analysis of the compounds, and to confirm the previous results. An aqueous solution was first tried,

but found to occasion loss of weight, on account of the long boiling required; an alcoholic solution was, therefore, prepared, by *thoroughly saturating* a strong alcoholic solution of sulphide of potassium and hydrogen, by transmitting the gas until it would absorb no more, and ceased to give a precipitate in sulphate of magnesia. As, however, the reduction was found to proceed easily at ordinary temperatures, it proved better to effect the change by continuing the immersion for twenty-four hours, and thus to avoid the risk of decomposition and loss which prolonged seething occasioned. That the cotton so obtained was free from nitrogen-compounds was proved by strongly heating it with caustic potassa, and conducting the gases evolved into a solution of litmus very faintly reddened, when the color remained unchanged; by the close correspondence in the quantity obtained from gun-cotton with that originally used, or the restoration back to the original weight; and by its possessing all the physical characters of common cotton, which differs from all products obtained from it by the action of acids in its depolarising action on light, and in its far greater softness and compressibility when wet, and also by the action of $\text{HO, SO}_3 + \text{HO}$, which dissolves the nitro-compounds, producing a solution which is not blackened below 212° , while common and reduced cotton are completely carbonised below that temperature.

Two combustions of the reduced cotton were made; one, in which the determination of hydrogen failed in consequence of an accident, gave, in one hundred parts, 44.4 of carbon; another, made by Mr. HARDWICK, yielded—

	Found.	Calculated.
Carbon,.....	44.86	44.44 = 12 C.
Hydrogen,.....	6.64	6.17 = 10 H.
Oxygen,.....	48.50	49.39 = 10 O.
	100.00	100.00

The other products of the equivalents of KS, HS are nitrate of potassa—KO, NO₃—and a little ammonia. No trace of nitrate could be discovered in the solution, which was evaporated to dryness with excess of acetic acid, to expel the nitrous acid. An attempt was made to turn the reaction of KS, HS upon gun-cotton to account in effecting the determination of the nitrogen by this means; but the results were unsatisfactory, in consequence of the co-existence of ammonia and nitrous acid in the liquid. The solution could not be heated to expel the former without risk of loss in the weight of the reduced cotton, neither could the ammonia be retained by addition of an acid, without escape of NO₂, from the action of sulphide of hydrogen and nitrous acid on each other.

A mode altogether different was, therefore, adopted, which consisted in making a solution of the compound in pure sulphuric acid, and, after conversion of the oxides of nitrogen into nitric acid, by means of some oxidating agent, estimating its amount by the method of PELOUZE, depending on its property of converting proto into sesquichloride of iron, and from the amount of the latter calculating the former. Before performing this, the properties of a solution of gun-cotton in sulphuric acid were examined. A portion immersed in cold concentrated sulphuric acid soon dissolves, with-

out evolution of any gas, producing a clear, colorless liquid; if this be poured at once into five or six times its bulk of water, so that the temperature does not rise before dilution takes place, the clear menstruum obtained gives no evidence whatever of nitric acid, or any oxide of nitrogen, even though raised subsequently to the boiling point; neither does it discolor a solution of permanganate or chromate of potassa. If, however, the original liquid in concentrated acid be diluted with only once, or even twice its bulk of water, a violent effervescence ensues, with abundant evolution of nitrous acid— NO_2 —or peroxide of nitrogen— NO_4 —together with carbonic acid. If, again, the solution in strong acid be heated before dilution, carbonic acid is evolved, while the oxides of nitrogen are retained, provided that the sulphuric acid is in different excess; if it now be diluted with water, nitric oxide— NO —escapes with effervescence. It became necessary, therefore, to effect the complete conversion of the nitrogen oxides into nitric acid. After trial of various oxidising agents, the object was successfully attained by the bichromate of potassa, which immediately peroxidises NO_2 and NO , but is without action on NO_4 : hence it was necessary to use a solution of gun-cotton in pure sulphuric acid made *in the cold*, which was then added to a strong solution of bichromate contained in a retort; the mixture—which immediately acquired a dark-green tint, from reduction of the chromic acid—was carefully distilled, precaution being taken to insure the entire expulsion of the nitric acid, which was then estimated, as above stated, by PELOUZE'S method.

The quantity of cotton in a given sample of gun-cotton having been determined by reduction by KS , HS , and the nitrogen by the above method, it is easy to see whether the compound contains any equivalents of NO_5 , not displacing a like number of equivalents of HO . The following results of analysis leave no doubt that it is purely a substitution-compound:—

Compound A.—Produced by action of the strongest acids, and most probably by repeated immersion in any mixture not weaker than $\frac{\text{HO, NO}_5}{2(\text{HO, SO}_3)} + 3\text{HO}$. Quite insoluble in any mixture of ether and alcohol, but soluble in acetic ether. Highly explosive.

- I. 27.5 of pure cotton gave, by three hours' immersion in strongest acid, 49.88 first time; 49.6 second time.
- II. 6.85 of this gun-cotton gave, by reduction, 3.78 of cotton.
- III. 6.37 of gun-cotton, by reduction, gave 3.48 of cotton.
- IV. 20.50 of gun-cotton gave $\text{NO}_5 = 10.84$.

	By analysis.			By calculation. $\text{C}_{36}\text{H}_{21}\text{O}_{30.9}\text{NO}_4$
	I.	II.	III.	
Cotton found,...	55.13	54.6	55.19	54.54
$\text{NO}_4 - \text{H}$,.....	—	—	44.07	45.46
			99.26	100.00

The composition of cotton being fully determined by the analyses of MITSCHERLICH, PELOUZE, and PAYEN, to be in the proportion of $\text{C}_{12}\text{H}_{10}\text{O}_{10}$, the preceding analysis would give rise to the formula,

100 of cotton produced 181.34: by calculation, 183.3.

Compound B.—Produced most probably by any acids of composition intermediate between

That which was examined was obtained by several immersions in $\frac{\text{HO, NO}_5}{2(\text{HO, SO}_3)} + 3\frac{1}{2}\text{HO}$. It is explosive, yet perfectly soluble in ether + $\frac{1}{8}$ alcohol; quite insoluble in acetic acid.

- I. 27.6 grains of cotton gave, by first immersion in the above mixture, 46.2 grains; by the second immersion, 47.1; by the third, 47.31.
- II. By reduction, 6.08 grains of the compound gave 3.50 of cotton.

	From synthesis. I.	By analysis. II.	Calculated. $\text{C}_{36}\text{H}_{22}\text{O}_{30.8}\text{NO}_4$
Cotton found,.....	58.34	57.56	57.45
$\text{NO}_4 - \text{H}$,.....	—	not determined.	42.55
			100.00

Formula would be $\frac{\text{H}_{22}}{\text{C}_{36}\text{O}_8\text{NO}_4} \text{O}_{30} = 846$.

100 of cotton produced 171.4; by calculation, 174.

Compound C.—Produced by $\frac{\text{HO, NO}_5}{2(\text{HO, SO}_3)} + 4\text{HO}$.

Like the preceding, this compound is very soluble in ether, but differs from it in being likewise perfectly soluble in *glacial acetic acid*. In this, as in the former compounds, the cotton fibre is quite uninjured. It is highly combustible rather than explosive, and burns with a slow jet of flame when rammed into a tube and ignited.

- I. 24.1 grains of cotton weighed, after first immersion, 38.26; after second immersion, 39.26; after third immersion, 39.53.
- II. By reduction, 9.94 grains of the compound gave 6.00 of cotton.

	By synthesis. I.	By analysis. II.	By calculation. $\text{C}_{36}\text{H}_{23}\text{O}_{30.7}\text{NO}_4$
Cotton found,.....	60.96	60.36	60.67
$\text{NO}_4 - \text{H}$,.....	—	not determined.	39.33
			100.00

Formula, $\frac{\text{H}_{23}}{\text{C}_{36}\text{O}_7\text{NO}_4} \text{O}_3 = 801$.

100 of cotton produced 164.0: by calculation, 164.8.

Compound D.—The existence, composition, and identity of this compound with xyloidin, are inferred from the following reasons:—

1st. There is a compound lower than C, since $\frac{\text{HO, NO}_5}{2(\text{HO, SO}_3)} + 4\text{HO}$ produces, by one immersion, an increase of only fifty-nine per cent., yet this product is perfectly soluble; if, however, C were the last, all products not attaining sixty-four per cent. in their amount of increase would contain unchanged cotton, and would be only partially soluble.

2nd. The product of the action of $\frac{\text{HO, NO}_5}{2(\text{HO, SO}_3)} + 5\text{HO}$, in which the texture of the cotton is more or less destroyed, is only partially soluble in ether—cotton, apparently unchanged, remaining behind; it thus appears that the soluble portion is the lowest compound obtainable by the actions of mixed acids on cotton.

3rd. As the next number in the series, its composition would be $C_{36} \left\{ \begin{smallmatrix} H_{24} \\ 6 NO_4 \end{smallmatrix} \right\} O_{30}$, which exactly corresponds with that assigned to xyloidin; and one hundred of cotton should yield 155.5. The soluble portion of these products further corresponds with xyloidin in giving an *opaque* film on drying, and in its solubility in glacial acetic acid. Although the xyloidins of woody fibre and starch agree in composition, they may be distinguished by the action of KS, HS, which reduces each to its proximate constituents, when the usual reaction with iodine may be obtained in the one case, but not in the other.

The modifications produced by the action of hot acids have not yet been examined; there is in these cases greater difficulty of avoiding loss in washing, in consequence of their disintegrated state, if immersed sufficiently long to obtain definite compounds. It is evident, however, that there are at least two, produced respectively by $\left\{ \begin{smallmatrix} HO, NO_5 \\ 2 (HO, SO_3) \end{smallmatrix} \right\} + 3 HO$, and $+ 4 HO$, since the former becomes insoluble after drying, while the latter remains soluble. All the compounds soluble in ether give transparent films on drying, except D. The presence of this last-named compound is one of the causes of opacity on the drying of some collodions; the other causes are, water in the alcohol or ether, or the presence of acetic ether. All these compounds may be prepared with mixtures containing much larger proportions of sulphuric acid and water; but these have the disadvantage of rapidly dissolving the compounds if used warm.

While endeavoring to ascertain the state in which nitrogen exists in these compounds, HADOW was led to examine the action of caustic potassa on the highest compound, with which, as is well known, it produces a solution capable of reducing salts of silver to a mirror-like surface upon the vessel that contains them. The decomposition of gun-cotton by a solution of potassa takes place slowly at ordinary temperatures, but almost instantly on raising it to 160°. Each portion then immersed causes a considerable extrication of heat, by which the temperature is soon raised to the boiling point, and ammonia is evolved with effervescence. In making the solution for examination, the temperature was kept at 150°, to avoid the formation of secondary products. At this point the gun-cotton quietly disappears without effervescence, producing at last a dark viscid fluid. This was diluted, neutralized with acetic acid, and precipitated by neutral acetate of lead. The filtrate gave a further abundant precipitate with the basic acetate, from which it was at first concluded that there were two distinct acids present; this, however, was afterwards found to arise from the solubility of the plumbous deposit in the acetate of potassa that had been formed, from which solution the basic acetate again throws it down. The liquid filtered from both precipitates contained nitrite and nitrate of potassa. The lead precipitates, after thorough washing on a linen filter, were diffused through water, and decomposed by sulphide of hydrogen, during which process effervescence occurred, with escape of NO_2 , showing that, notwithstanding the washings the deposits had

undergone, they still retained a portion of nitrate. The brownish solution obtained was again precipitated by acetate of lead, washed, and decomposed as before, when a pale yellow, strongly-acid liquid was obtained, retaining the original reducing power upon the salts of silver unimpaired, and capable of rapidly decomposing carbonates with effervescence. Its power of forming crystalline salts was examined by slowly evaporating a solution of the compound on a slip of glass, and viewing it under a microscope. The ammonia-salt appearing to be the most promising, the liquid was neutralized with ammonia, and allowed to evaporate *in vacuo*. After some time, little tufts of prismatic crystals formed. On examination, however, these were found to be devoid of reducing power, and proved to be oxalate of ammonia. That the oxalic acid had not been formed by the subsequent processes was proved by detecting it in the original solution of gun-cotton in cold aqueous potassa. The liquid, freed from oxalic acid by nitrate of lime, was found to possess many of the characteristics of saccharic acid, such as its property of carrying down nitrites with its lead salts, and its reducing power on salts of silver, which is manifested in both cases on adding to the respective menstrua a portion of a solution of nitrate of silver, ammonia sufficient to cause a clear liquid, and subsequently caustic potassa, without which in either case no mirror-like deposit will take place even on boiling. In certain proportions the color of the reduced silver is identical. Like the neutral saccharates, the neutral salts of this acid, which might be termed pyroxylic acid until its identity with some other is proved, likewise give precipitates with salts of lime, baryta, and cadmium. The principal differences between the two acids are, that no crystalline acid pyroxalate of potassa could be obtained, the solution drying *in vacuo* to a gummy mass, whereas the acid saccharate is very easily crystallised; and that the saccharates of the above-mentioned bases are far more soluble in the heat than in the cold, and are visibly crystalline under the microscope; while the pyroxalates of lime and baryta are but slightly soluble on warming the liquid, and that of cadmium does not redissolve at all on the mere application of heat, though, like the saccharate, it is readily soluble in an excess of the salt of cadmium. The precipitates are likewise all amorphous, with the exception of the lime salt, which has the form of little nodules. HADOW could not further examine the properties of this acid, or obtain a compound with the certainty of its being sufficiently pure for analysis, in consequence of the want of crystalline form and the obstinacy with which a portion of coloring matter is retained.—*Hadow*.

COLLODION.—This substance, which is formed by dissolving gun-cotton in spirit, has of late years been extensively employed in the manner subsequently stated, under the uses of gun-cotton. The following are the best proportions for making it:—

	Parts by weight.
Prepared cotton,	8
Rectified ether,	125
Rectified alcohol,	8

Put the cotton with the ether into a well-stopped

bottle, and agitate the mixture for some minutes. Then add the alcohol by degrees, and continue to shake until the whole of the liquid acquires a sirupy consistence. It may be then passed through a cloth, the residue strongly pressed, and the liquid kept in a well-secured bottle.

Collodion thus prepared possesses remarkably adhesive properties. A piece of linen or cotton cloth covered with it, and made to adhere by evaporation to the palm of the hand, will support, after a few minutes, without yielding, a weight of from twenty to thirty pounds. Its adhesive power is so great, that the cloth will commonly be torn before it gives way. The collodion cannot be regarded as a perfect solution of the cotton. It contains, suspending and floating in it, a quantity of the vegetal fibre which has escaped the solvent action of the ether. The liquid portion may be separated from these fibres by a filter, but it is doubtful whether this is an advantage. In the evaporation of the liquid, these undissolved fibres, by felting with each other, appear to give a greater degree of tenacity and resistance to the exsiccated mass.

In the preparation of collodion it is indispensable to avoid the presence of *water*, as this renders it less adhesive; hence the ether, as well as the alcohol, should be pure and rectified. The parts to which the collodion is applied should be first thoroughly *dried*, and no water allowed to come in contact with them until all the ether is evaporated.

A method for the preparation of elastic collodion is given by LAURAS. He prefaces it as follows:—

The important improvement to be made in this compound, which hitherto has not been of very frequent application in therapeutics, consists in giving efficacy to it, and in preventing the sufferings produced by its application on any portion of the body, and principally on the articulations, which are much constricted after having been covered with it—an effect due to its want of suppleness and elasticity, and which the skin requires both for stretching and contracting.

By adopting the following formula, every inconvenience is obviated, collodion becomes easy of employment, and enables the patient to move without suffering pain:—

Sulphuric acid, of specific gravity 1.847, three hundred grammes; dry nitrate of potassa, two hundred grammes. These are both mixed together in a stone-ware or porcelain pot, and ten grammes of carded cotton added.

Leave in contact for twelve minutes; withdraw the cotton, wash it with cold water to remove the acid which it retains, and after two or three rinsings, immerse it in water containing thirty grammes of carbonate of potassa in solution in one hundred grammes of water; plunge it again into ordinary water, agitate well, and dry at a temperature of 77° to 86°.

The cotton thus prepared takes the name of Xyloidin, and may afterwards be mixed with the ether and the other substances which form it into elastic collodion.

Elastic Collodion.—Xyloidin eight grammes, ordinary ether one hundred and twenty-five grammes. Place in a wide-mouthed flask, and add alcohol of specific gravity .825 eight grammes. Agitate, and then make

a mixture composed of Venice turpentine two grammes; castor oil two grammes; white wax two grammes; ether six grammes. Heat together the first three substances, add the ether, and combine the two mixtures.

ADULTERATION.—Should it be desired to ascertain whether ordinary carded cotton has not been added to sophisticate the gun-cotton, it may be arrived at by the following micro-chemical process. A small portion of the cotton is impregnated with a solution of iodine, and a drop of sulphuric acid added, and then submitted to the lens; the gun-cotton is very feebly affected by this treatment, and retains the yellow coloration communicated by the iodine only slightly intensified after some time, whilst under the same treatment the fibres of ordinary cotton would quickly disintegrate, and partake of a lively violet hue. The intensity of the latter will be a comparative indication of the probable amount of the adulterants.

USES.—Many attempts have been made to apply gun-cotton to mining purposes on account of its enormous explosive force, and the small quantity of smoke which it produces; but the objections to its use are numerous, the most fatal one being its liability to spontaneous ignition.

Gun-cotton continues to be an object of great interest on account of its application to the beautiful art of photography. When the cotton is prepared in such a way as to burn slowly, it is not liable to spontaneous ignition, and it is in this state perfectly soluble in ether, which the more explosive cotton is not. If the ethereal solution be poured on the surface of cold water, a paper is produced, which is prepared for the use of the photographer. This paper is a very active electric, and is perfectly soluble in ether. Collodion has also been made use of in surgery, by applying the ethereal solution to a wound, when a thin delicate artificial skin is formed by it, which perfectly excludes the air.—*Encyclopædia Britannica*.

GUNPOWDER.—*Poudre à canon*, French; *Schiesspulver*, German.—The article which bears this title is a singular mixture of nitrate of potassa—saltpetre—sulphur, and charcoal, and is so well known for its remarkable properties by every one, that it is unnecessary to enter into a detailed exposition of it. Regarding its manufacture and the uses to which it is devoted, however, in a true light, its importance as an agent of power, which places it side by side with steam at the present day, cannot fail to render it an object of deep research and inquiry.

It might well be said that no other branch of industry has, during many years, decided the destinies of people so much as gunpowder. Sometimes favorable to the progress of civilization, powder offers to the miner and engineer a ready and sure means of breaking all obstacles which intercept their progress in their labors; sometimes, on occasions of festivity, it becomes in the hands of the artificer a symbol of joyful public rejoicings; and, finally, on occasions of civil strife and warfare, it turns out to be a sure instrument of death and massacre—spreading the devastating bullet or shell with an effect which lays nations of greatness and pomp level with the dust, and raises others to the dignity of empires.

The invention of gunpowder formed a grand epoch in the world's history. TOMLINSON ascribes it to BARTHOLO SCHWARTZ, a German monk and alchemist, and the date of the discovery is supposed to be about the year 1320. The prior claims of ROGER BACON, whatever they be, are, however, unquestionable, as this substance is described in his writings about the year 1270, or half a century before the supposed discovery by SCHWARTZ. But even BACON himself has as little title to the invention as his imagined rival; nor, indeed, when his own description of this then wonderful compound is examined, can it be perceived that he makes any claim to be the discoverer. On the contrary, he quotes it as a well-known substance in common use all over the world, for making squibs for the amusement of children—so pertinacious are vulgar errors. DUTENS attempts to show that the claim, which certainly does not belong to BACON, is removed to MAGNUS GRÆCUS, whose manuscript he quotes, and from which he presumes BACON derives his knowledge of the invention; although, by his own showing, BACON need not have consulted an obscure writing for an invention of general notoriety. In the same manuscript are contained directions for making a rocket, which are such as to prove that the nature of this firework was thoroughly understood. It is even remarkable that he recommends the charcoal of willow wood, which the moderns have found by experience to be amongst the best for such purposes.

Thus far the date of the origin of gunpowder has been traced, not only beyond BACON, but beyond this supposed predecessor, as he himself professes to be a compiler, not an author of the *Liber Ignium*, as he denominates his treatise. If, in attempting to ascend still higher, the evidence becomes more rare and illegible, there are still insuperable facts to prove that its antiquity is far greater, however impossible it may be to approximate to the date of the invention, much less to assign that which appears to be buried amongst the obscurities of oriental learning. The question of gunpowder as applied to artillery is a separate one; but there is abundant reason to believe that this compound was not only used in some form or other as an explosive and combustible substance, but that it was applied even to military purposes—it may be, in the shape of rockets or other fireworks, which, for objects of amusement at least, have been familiar to the Chinese beyond all record.

The earliest date to which the knowledge of gunpowder can be referred, in defect of a sufficiently remote acquaintance with oriental history, is 355 before Christ, although, from the very nature of this attestation, it follows that it was then not only known to the Eastern nations, but that it must have long been so, since, even at that early period, it was applied to warlike purposes. In the code of Hindoo laws, indeed, where it is mentioned, it is referred to an era which oriental antiquaries have considered as coincident with the time of MOSES. But the evidence to which more particular allusion is made, is found in a passage of the *Life of Apollonius Tyanæus* by PHILOSTRATUS, the purport of which is that ALEXANDER was unwilling to attack the Oxydracæ, who lived between the Hyphasis and the Ganges, be-

cause they were under the care of the gods, and overthrew their enemies with thunder and lightning which they shot from their walls. The same account is given of the repulses experienced in this country by HERCULES and BACCHUS.

The next of these early dates, in which also the evidence is imperfect, is 212 before Christ; but the establishment of the proof of the last would render this one more credible. In the defence of Syracuse by ARCHIMEDES, VITRUVIUS relates that one of his engines threw stones with a great noise—a description which does not apply to any of the mechanical artillery of the ancients. On a notice so superficial, however, much stress must not be laid, and here ends all the information respecting the earliest knowledge of gunpowder. It seems, however, so decidedly capable of being traced from the East, through the intervention of the Arabs, that there can be little doubt of its oriental origin, and of its being thence imported into Europe. Indeed, the military use of rockets in the armies of India ascends to a very remote period.

Of the earliest date at which it was known in China, their own evidence is defective; but UFFANO, an Italian author, affirms that not only gunpowder, but ordnance, was in use in that nation in the year 85, and that in his day cannon were remaining from the most ancient times in some of the maritime provinces, made both of iron and of brass. Hence some writers presume that the Chinese communicated the invention to the Indians; whilst it has also been said, but on no sufficient authority, that they themselves received it from Tartary—a nation respecting which little or nothing is known and in which one would not be inclined to look for an early acquaintance with the arts. This, however, refers to a date so late as 917; so that, if there is any dependence to be placed on the Indian and Chinese hypothesis, the Tartars must themselves have borrowed the invention from those to whom they are said to have lent it.

There is after this a long blank; and the first author on the subject is an Arabic writer, in the Escorial collection, whose work, bearing date 1249—about twenty years before the date of BACON's narrative—is translated by CASIRI. His description is such that it may apply both to rockets and to shells. In the former case, it only involves the knowledge of the detonating compound; the latter, were it proved, would show that they were also acquainted with the use of ordnance, although it is not impossible but that such projectiles might have been thrown by mechanical artillery.

As the invention of gunpowder has been popularly ascribed to BACON and to SCHWARTZ, so the use of ordnance has been referred to the time of the battle of Cressy—1346. To pass over the Chinese hypothesis on this part of the subject, it will be found that cannon were known at least as early as the year 1312. This is derived from the source quoted by CASIRI; from Arabian writers who in 1312 and 1323 describe the use of ordnance; whilst, if BARBOUR is to be trusted, EDWARD III. was also provided with some pieces of artillery in 1327, and Père DANIEL asserts that cannon were known to the French in 1338. This discussion need not be carried lower; though, in favor

of the oriental origin of the invention, it may be remarked, that artillery was much in use in the Mediterranean when it was still but little used elsewhere; as by the Venetians in 1380 against Genoa, and by ALPHONSO XI. in his wars with the Moors.—*Encyclopædia Britannica*.

In the prolegomena it was stated that gunpowder is a composition of definite quantities of sulphur, saltpetre, and charcoal. From time to time various experiments have been conducted with considerable care for the sake of determining the most convenient proportions of the foregoing substances; and, singularly enough, people have, in almost every instance, fallen back upon the recipes given by the most ancient writers upon the production of this article. The knowledge that powder owes its extraordinary effects to the sudden transformation of its solid constituents into permanent gases, the volume of which is enlarged by the temperature resulting from the chemical action producing this change, will at once lead to the conclusion, that all matters incapable of undergoing such a modification injure or depreciate, in proportion to their quantity, the quality and efficacy of the product. Hence it should always be the desire of the manufacturer to use the purest materials; and, to assist him in his business, they will be considered here.

MATERIALS.—The greatest care is requisite in the preparation of pure ingredients for the manufacture of gunpowder.

The principal saline impurity in saltpetre is chloride of sodium—common salt—which has a very injurious action upon gunpowder, causing it to absorb moisture, whereby its power is soon considerably weakened. Saltpetre containing more than a three-thousandth part of chlorides, is rejected as unfit for use.

The solubility of saltpetre at 212° is about fourteen times greater than it is at ordinary temperatures, while that of chloride of potassium is only about twice as great, and that of chloride of sodium is but slightly increased. If, therefore, a solution containing these three salts be concentrated, the greater quantities of the chlorides will be deposited as the water decreases, even before the nitrate of potassa exhibits any symptom of crystallizing out. This separation is effected in practice, by placing a perforated iron ladle or dish on the bottom of the boiler in which the solution is being concentrated. The chlorides, as they separate by the evaporation of the water, deposit upon the dish, and may from time to time be removed. When small needles of nitrate of potassa begin to appear, the menstruum is run off into the crystallizing cooler, from which tolerably pure saltpetre will be obtained, to be refined by a similar operation.

At Waltham Abbey the refining of saltpetre is effected by first decolorizing its solution by ebullition with newly-burnt charcoal, and then by repeated crystallization. Great care must be exercised in this process, which will be fully dwelt upon under POTASSA.

Sulphur, as employed for the manufacture of gunpowder, is generally in the sublimed state, or that known in common parlance as *flowers of sulphur*. These are obtained by conducting the vapor of sulphur into large chambers, the sides of which must

be kept cool. The sulphur condenses in the form of a fine crystalline lemon-yellow powder. When the sides of the chamber become heated, the sulphur fuses, becomes limpid, and trickles down to the base of the chamber. To prevent this, which, of course, would spoil the whole deposit of flowers, as soon as the walls of the chamber get too warm, the communication between the latter and the retort is closed, and another one opened, leading into a metal receiver; the sulphur is allowed to distil over into this until the first chamber has become sufficiently cool, and the flowers have been collected from its sides, when the vapors are again passed into it.

The sublimed sulphur sometimes requires washing, in order to free it from the sulphuric acid which is generally formed with it, and which is caused by the oxidation of the sulphurous vapors by means of the common air which pervades the condensing chamber previous to the commencement of the distillation of each charge.

It has been suggested that the sulphuric acid should be removed by allowing the sulphur to remain between damp cloths for some time previous to use.

Charcoal.—The third principal constituent of gunpowder is charcoal reduced to an impalpable state. This constituent demands no less attention in the selection than the other components; for much of the efficiency of the powder depends upon its possessing such qualities as experience has shown to be required. Even in the time of MAGNUS GRÆCUS, as already mentioned in the preceding historical notice, the charcoal of willow-wood was preferred, and experience has fully proved that the charcoal of the soft woods always produces the best results. Some time since, dogwood was adopted, as giving the most friable charcoal; but it has since been shown that the woods of the willow, poplar, black alder, and chestnut trees afford equally suitable products. The hard woods are invariably rejected, and with justice; though the presence in them of deleterious salts is not the only objection to their use.

Two considerations must not be overlooked in choosing a proper charcoal—namely, the nature of the wood, and the manner in which the carbonization of the same is conducted; and each demands the utmost circumspection in the manufacturer who is desirous of producing an article which will yield the greatest possible amount of force, and combine at the same time the quality of inflaming readily, as well as that of leaving the least quantity of residuary matter after its ignition.

There is no doubt, says the writer of the article GUNPOWDER in the *Encyclopædia Britannica*, that wood which contains carbonate of potassa or other deliquescent salts, is unfit for the purpose, and for obvious causes. This is the case in the oak, elm, fir, and other trees. But there is another reason for the badness of these kinds of charcoal, which is not so obvious, although it is evidently connected with their hardness. It appears to depend on the small proportion of hydrogen combined with the carbon in these charcoals, compared to that which exists in the produce of the softer woods. Even these can be reduced to the same state by subjecting them to higher temperatures. Thus the hydrogen is dissipated, the charcoal becoming

so hard as to scratch steel; in which case, however obtained, it is unfit for gunpowder.

Thus experience has found, from time to time, how ill-adapted for this manufacture are many of the charcoals usually prepared; but such acquisitions were frequently gained at the expense of a loss sustained by the failure of some experiment. In later times, however, scientific research clears the path for the manufacturer to some extent, so that he who desires to progress has not to confide in the results of haphazard experiments, the principles of which may be but ill understood, but rather decide according to the conclusions drawn from the well-contrived investigation on the subject. PROUST is one of those who has made the materials and preparation of gunpowder his study, and from them considerable information may be gained. With the view of finding the best quality of charcoal, he practised the following ready and simple means. He makes a mixture of twelve grains of the charcoal and sixty-two of nitrate of potassa by careful grinding in a mortar, and then introduces it on a small tray into a copper tube two and a half inches in length by three lines in diameter; he primes on the top of this with a little fowling powder, and when this is done, the lower part of the tube is fitted in a dish of cork, or other light material, which is floated on the surface of water. It is evident from these arrangements, analogous as they are to those under which the powder is inflamed, that the mixture which burns the more readily is that which is most suited to the manufacture. By experiments conducted in this way, and with all the precautions available under the circumstances, PROUST obtained the following results:—

Mixture of sixty-two grains of saltpetre and twelve of charcoal.	Time of the combustion in seconds.	Weight of residue in grains.
From hemp or hemp husk, . . .	10	12
“ stalks of asphodel,	10	12
“ vine branches,	12	20
“ pea stalks,	13	21
“ pine,	17	30
“ bourdaine,	20	24
“ spindle-tree,	21	27
“ hazle,	23	30
“ maize canes,	25	38
“ chestnut-tree,	26	36
“ walnut-tree,	29	33
“ maize,	55	43
“ coal-coke,	50	45
“ sugar,	70	48

When submitted to the same operation, he found that the charcoal produced from starch, wheat, rice, gall-nuts, indigo, gluten, gelatin, albumen, blood, and skin, and, in fact, those derived from all animal matters, would not undergo combustion.

From the foregoing table it is evident that those which precede the charcoal from hazlewood rise in the scale of superior fitness, whilst those beneath the latter evidently descend, and are not well adapted for the manufacture.

Other experiments upon the same subject, founding the comparison of the different charcoals upon the volume of gas which they yielded when ignited with saltpetre, have been conducted by French and British chemists, and the results are tabulated below. In each case the proportions used by the former were sixty grains of nitrate of potassa to twelve of charcoal; but

in the latter the calculations are made to correspond with the same standard:—

Charcoal.	Proportion of gas in cubic inches.	Residue in grains.
From French hemp stalks, . . .	62	12
“ asphodel,	62	20
“ vine,	64	20
“ pea stalks,	62	21
“ spindle-tree,	66	28
“ fir,	66	30
“ chestnut,	66	36
“ hazle,	66	33
“ lamp-black,	54	44
“ coke,	54	45
“ filbert,	72	30

Much of the interest which might otherwise be taken in the foregoing results of the French chemists is lost, on account of the subjects being not likely ever to enter practically, at least to any extent, into the manufacture under consideration. Below are given results arrived at in England, by operating upon the more frequently-occurring woods:—

	Proportion of gas
Filbert,	72
Oak,	61-63
Mahogany,	58
Elm,	62
Willow— <i>Salix Alba</i> ,	76-78
Alder,	74-73
Dogwood— <i>Rhamnus frangula</i> , . . .	80-82-84
Oak bark,	58
Animal charcoal,	50-46-42-40
Coke,	52-48
Lamp-black,	54-52
Oak charcoal overheated,	54-56
Willow “ “	59 64-66

TOMLINSON attributes much of the difference in the latter table to the method in which the charcoal is prepared, rather than to the substance itself, since he considers that to overheat the matter in its carbonization is injurious to its power of combustion. This is evidenced by the results which the modified charcoal from oak and willow afforded; and, in fact, several researches have led to the acknowledgment of the same fact. VIOLETTE has shown that the most combustible charcoal loses this quality in proportion as the heat applied in the carbonization is raised, till ultimately, when the charring is made at the fusing point of platinum, the product obtained is so incombustible as to be ignited with difficulty even when the heat is 2282°. During his researches upon the carbonization of wood and the application of charcoal, he examined with considerable skill and acuteness the various products which most of the ordinary woods afford by charring, in reference to their combustibility in air, and the temperature of their ignition according to the caloric applied in their manufacture, and also with regard to the same kind of charcoal when subjected to an increasing heat in close vessels; the temperature at which charcoals decompose nitrate of potassa, as well when they are the result of a standard degree of heat, as when this degree has been varied in their manufacture. To these researches he has coupled the estimation of the necessary caloric required for sulphur to decompose the saltpetre, and that at which it burns in air, and many others; such as the thermometric degree at which powder is ignited, the several mixtures used for the manufacture of powder with regard to the amount of their constituents, *et*

cetera, to which reference will be made in their respective places. As the susceptibility of charcoal taking fire is a subject which, to those who are under the necessity

of storing it for some time in magazines, is highly interesting, it may be well to lay before the reader the procedure of VIOLETTE, for the estimation of the degree of heat at which charcoals enter spontaneously into combustion.

He adopted an apparatus similar to Fig. 246, in which A is a small flat plate-iron basin, floating upon a bath of tin or pewter, B, which is heated by a fire

at C. The pieces of charcoal, prepared in pellets 0.01 inches in length and 0.001 in thickness, were placed symmetrically in the basin, A, and the fire urged, thus increasing the heat of the tin bath, and, consequently, that of the small iron basin containing the cylinders of charcoal. The order of their inflammability was noted as each, in succession, gave indications of combustion by a luminous point appearing upon the circumference of the superior section, and which quickly enveloped the whole surface, and resulted in leaving only the ash. In the following table, the series in the column A show the order of the spontaneous ignition of the materials which had been thoroughly charred, whilst those in B represent the order with reference to brown charcoals, or such as retained a portion of their constituents, and, therefore, had only been but imperfectly made:—

SERIES A.

The order of the ignition of charcoal.	Temperature of the carbonization of charcoal.	
1	500°	500°
2	270°	518
3	280	536
4	290	554
7	300	572
9	310	590
10	320	608
11	330	626
12	340	644
13	350	662
21	432	819
22	1023	1873.6
23	1300	2372
24	1500	2732

SERIES B.

The order of the ignition of charcoal.	Temperature of the carbonization of charcoal.	
"	"	"
5	250°	482°
6	230	446
8	240	464
14	220	428
15	210	410
16	190	374
17	170	338
18	200	392
19	180	356
20	160	320

From the above, it may be inferred that charcoal, prepared at 500°, is the most liable to undergo spontaneous combustion. It is remarkable that the phenomena observed with regard to the brown or torrefied woods in the second column, before their entering into ignition of complete carbonization, was effected first, as indicated by the quantities of fumes which were disengaged from them; *id est*, they were converted into a charcoal such as that prepared at 500°. As soon as this condition was attained, they underwent spontaneous ignition. In the second place, it is easy to see that the inflammability of the charcoals decreases in proportion as the temperature of their preparation is more elevated. To make the examination more definite than the comparative but necessarily indeterminate one above mentioned, the following process was followed:—A porcelain crucible was selected, and about sixty grammes of saltpetre fused in it. The bulb of a mercurial thermometer immersed in it, showed that the melting occurred at 644°. Gradually pieces of the most inflammable charcoal, such as those prepared at 500°, were projected into the molten mass, and the crucible quickly inclosed to prevent cooling by radiation; on taking the cover off, the particles of charcoal were observed to be undergoing several commotions, but without taking fire, notwithstanding that, by increasing the heat only 1.8°, the matter burned. Hence it may be stated, that charcoal obtained at 500° ignites spontaneously at 645.8° or 646°. On increasing the temperature of the crucible and nitrate of potassa by

regular increments of heat, it was found that charcoals prepared at temperatures from—

500° to 536°	ignited at 680°
536 to 662	" 698

On raising the heat a little above 698°, the charcoal resulting at 819° ignited, but the other kinds, produced at a higher heat, refused to burn. As the thermometer ceased to indicate truly any higher heat, the bath had to be changed for one of pewter or tin. Having introduced the more incombustible charcoals, then gently raised the temperature with a charcoal fire till near the point of redness, they began to show the first signs of combustion.

In the annexed table the results are tabulated:—

The temperature at which charcoal has been carbonized.		The temperature at which the charcoals have taken fire.
260° = 500°	340° — 680°
270 = 518	}	340 to 360 — 680 to 698
280 = 536		
290 = 554		
300 — 572		
310 — 590	}	360 to 370 — 698 to 716
320 — 608		
330 — 626		
340 — 644		
350 — 662	}	600 to 800 — 112 to 1472
432 — 819		
1023 — 1873.6		
1250 — 2282		
1300 — 2372	}	1250 — 2280
1500 — 2732		
Charcoals made at temperatures which fuse platinum.....		

The foregoing determinations possess a peculiar interest for the powder manufacturer, especially when it is understood that frequently charcoal, produced at temperatures between 500° and 662°, are employed for the purposes of sporting powder; the black kinds obtained at a higher heat, such as 819° or so, being reserved for the article in demand for the military and mining requirements. Now, since the first kind ignites spontaneously at 680°, the origin of the various explosions happening in powder mills may be easily traced. The increase of temperature by friction during the grinding, more especially when this is done by metallic bodies, often reaches the preceding degree, and, consequently, supplies the necessary conditions for inducing combustion in the mass; again, when placed in the state of fine powder in the recipients, it condenses so much air in its pores that the heat, which is a well-known result of such a condensation, is sometimes elevated to the above standard. Probably the compression referred to is not made without a chemical combination of a part of the oxygen with the hydrocarbon in the charcoal, and such slow combustion, gathering greater force as it progresses, may be in the end sufficiently active to ignite the whole mass.
